Series Foreword

The goal of building systems that can adapt to their environments and learn from their experience has attracted researchers from many fields, including computer science, engineering, mathematics, physics, neuroscience, and cognitive science. Out of this research has come a wide variety of learning techniques that are transforming many industrial and scientific fields. Recently, several research communities have begun to converge on a common set of issues surrounding supervised, unsupervised, and reinforcement learning problems. The MIT Press Series on Adaptive Computation and Machine Learning seeks to unify the many diverse strands of machine learning research and to foster high-quality research and innovative applications.

The MIT Press is extremely pleased to publish this contribution by Ethem Alpaydın to the series. This textbook presents a readable and concise introduction to machine learning that reflects these diverse research strands. The book covers all of the main problem formulations and introduces the latest algorithms and techniques encompassing methods from computer science, neural computation, information theory, and statistics. This book will be a compelling textbook for introductory courses in machine learning at the undergraduate and beginning graduate level.

Preface

Machine learning is programming computers to optimize a performance criterion using example data or past experience. We need learning in cases where we cannot directly write a computer program to solve a given problem, but need example data or experience. One case where learning is necessary is when human expertise does not exist, or when humans are unable to explain their expertise. Consider the recognition of spoken speech, that is, converting the acoustic speech signal to an ASCII text; we can do this task seemingly without any difficulty, but we are unable to explain how we do it. Different people utter the same word differently due to differences in age, gender, or accent. In machine learning, the approach is to collect a large collection of sample utterances from different people and learn to map these to words.

Another case is when the problem to be solved changes in time, or depends on the particular environment. We would like to have general-purpose systems that can adapt to their circumstances, rather than explicitly writing a different program for each special circumstance. Consider routing packets over a computer network. The path maximizing the quality of service from a source to destination changes continuously as the network traffic changes. A learning routing program is able to adapt to the best path by monitoring the network traffic. Another example is an intelligent user interface that can adapt to the biometrics of its user, namely, his or her accent, handwriting, working habits, and so forth.

Already, there are many successful applications of machine learning in various domains: There are commercially available systems for recognizing speech and handwriting. Retail companies analyze their past sales data to learn their customers' behavior to improve customer relationship management. Financial institutions analyze past transactions

to predict customers' credit risks. Robots learn to optimize their behavior to complete a task using minimum resources. In bioinformatics, the huge amount of data can only be analyzed and knowledge be extracted using computers. These are only some of the applications that we—that is, you and I—will discuss throughout this book. We can only imagine what future applications can be realized using machine learning: Cars that can drive themselves under different road and weather conditions, phones that can translate in real time to and from a foreign language, autonomous robots that can navigate in a new environment, for example, on the surface of another planet. Machine learning is certainly an exciting field to be working in!

The book discusses many methods that have their bases in different fields; statistics, pattern recognition, neural networks, artificial intelligence, signal processing, control, and data mining. In the past, research in these different communities followed different paths with different emphases. In this book, the aim is to incorporate them together to give a unified treatment of the problems and the proposed solutions to them.

This is an introductory textbook, intended for senior undergraduate and graduate level courses on machine learning, as well as engineers working in the industry who are interested in the application of these methods. The prerequisites are courses on computer programming, probability, calculus, and linear algebra. The aim is to have all learning algorithms sufficiently explained so it will be a small step from the equations given in the book to a computer program. For some cases, pseudocode of algorithms are also included to make this task easier.

The book can be used for a one semester course by sampling from the chapters, or it can be used for a two-semester course, possibly by discussing extra research papers; in such a case, I hope that the references at the end of each chapter are useful.

The Web page is http://www.cmpe.boun.edu.tr/~ethem/i2ml/ where I will post information related to the book that becomes available after the book goes to press, for example, errata. I welcome your feedback via email to alpaydin@boun.edu.tr.

I very much enjoyed writing this book; I hope you will enjoy reading it.

Acknowledgments

The way you get good ideas is by working with talented people who are also fun to be with. The Department of Computer Engineering of Boğaziçi University is a wonderful place to work and my colleagues gave me all the support I needed while working on this book. I would also like to thank my past and present students on which I have field-tested the content that is now in book form.

While working on this book, I was supported by the Turkish Academy of Sciences, in the framework of the Young Scientist Award Program (EA-TÜBA-GEBİP/2001-1-1).

My special thanks go to Michael Jordan. I am deeply indebted to him for his support over the years and last for this book. His comments on the general organization of the book, and the first chapter, have greatly improved the book, both in content and form. Taner Bilgiç, Vladimir Cherkassky, Tom Dietterich, Fikret Gürgen, Olcay Taner Yıldız, and anonymous reviewers of The MIT Press also read parts of the book and provided invaluable feedback. I hope that they will sense my gratitude when they notice ideas that I have taken from their comments without proper acknowledgment. Of course, I alone am responsible for any errors or shortcomings.

My parents believe in me, and I am grateful for their enduring love and support. Sema Oktuğ is always there whenever I need her and I will always be thankful of her friendship. I would also like to thank Hakan Ünlü for our many discussions over the years on several topics related to life, the universe, and everything.

This book is set using LaTeX macros prepared by Chris Manning for which I thank him. I would like to thank the editors of the Adaptive Computation and Machine Learning series, and Bob Prior, Valerie Geary, Kath-

leen Caruso, Sharon Deacon Warne, Erica Schultz, and Emily Gutheinz from The MIT Press for their continuous support and help during the completion of the book.

Notations

x	Scalar value
$\boldsymbol{x}$	Vector
$\mathbf{X}$	Matrix
$\boldsymbol{x}^T$	Transpose
$\mathbf{X}^{-1}$	Inverse
X	Random variable
$P(X)$	Probability mass function when X is discrete
$p(X)$	Probability density function when X is continuous
$P(X\|Y)$	Conditional probability of X given Y
$E[X]$	Expected value of the random variable X
$\text{Var}(X)$	Variance of X
$\text{Cov}(X, Y)$	Covariance of X and Y
$\text{Corr}(X, Y)$	Correlation of X and Y
μ	Mean
σ^2	Variance
$\boldsymbol{\Sigma}$	Covariance matrix
m	Estimator to the mean
s^2	Estimator to the variance
$\mathbf{S}$	Estimator to the covariance matrix

$\mathcal{N}(\mu, \sigma^2)$	Univariate normal distribution with mean μ and variance σ^2
$\mathcal{Z}$	Unit normal distribution: $\mathcal{N}(0, 1)$
$\mathcal{N}_d(\boldsymbol{\mu}, \boldsymbol{\Sigma})$	d-variate normal distribution with mean vector $\boldsymbol{\mu}$ and covariance matrix $\boldsymbol{\Sigma}$
x	Input
d	Number of inputs: Input dimensionality
y	Output
r	Required output
K	Number of outputs (classes)
N	Number of training instances
z	Hidden value, intrinsic dimension, latent factor
k	Number of hidden dimensions, latent factors
C_i	Class i
$\mathcal{X}$	Training sample
$\{x^t\}_{t=1}^N$	Set of x with index t ranging from 1 to N
$\{x^t, r^t\}_t$	Set of ordered pairs of input and desired output with index t
$g(x\|\theta)$	Function of x defined up to a set of parameters θ
$\arg\max_\theta g(x\|\theta)$	The argument θ for which g has its maximum value
$\arg\min_\theta g(x\|\theta)$	The argument θ for which g has its minimum value
$E(\theta\|\mathcal{X})$	Error function with parameters θ on the sample $\mathcal{X}$
$l(\theta\|\mathcal{X})$	Likelihood with parameters θ on the sample $\mathcal{X}$
$\mathcal{L}(\theta\|\mathcal{X})$	Log likelihood with parameters θ on the sample $\mathcal{X}$
$1(c)$	1 if c is true, 0 otherwise
$\#\{c\}$	Number of elements for which c is true
δ_{ij}	Kronecker delta: 1 if $i = j$, 0 otherwise

1 *Introduction*

1.1 What Is Machine Learning?

WITH ADVANCES in computer technology, we currently have the ability to store and process large amounts of data, as well as to access it from physically distant locations over a computer network. Most data acquisition devices are digital now and record reliable data. Think, for example, of a supermarket chain that has hundreds of stores all over a country selling thousands of goods to millions of customers. The point of sale terminals record the details of each transaction: date, customer identification code, goods bought and their amount, total money spent, and so forth. This typically amounts to gigabytes of data every day. This stored data becomes useful only when it is analyzed and turned into information that we can make use of, for example, to make predictions.

We do not know exactly which people are likely to buy a particular product, or which author to suggest to people who enjoy reading Hemingway. If we knew, we would not need any analysis of the data; we would just go ahead and write down the code. But because we do not, we can only collect data and hope to extract the answers to these and similar questions from data.

We do believe that there is a process that explains the data we observe. Though we do not know the details of the process underlying the generation of data—for example, consumer behavior—we know that it is not completely random. People do not go to supermarkets and buy things at random. When they buy beer, they buy chips; they buy ice cream in summer and spices for Glühwein in winter. There are certain patterns in the data.

We may not be able to identify the process completely, but we believe

we can construct *a good and useful approximation.* That approximation may not explain everything, but may still be able to account for some part of the data. We believe that though identifying the complete process may not be possible, we can still detect certain patterns or regularities. This is the niche of machine learning. Such patterns may help us understand the process, or we can use those patterns to make predictions: Assuming that the future, at least the near future, will not be much different from the past when the sample data was collected, the future predictions can also be expected to be right.

Application of machine learning methods to large databases is called *data mining.* The analogy is that a large volume of earth and raw material is extracted from a mine, which when processed leads to a small amount of very precious material; similarly in data mining, a large volume of data is processed to construct a simple model with valuable use, for example, having high predictive accuracy. Its application areas are abundant: In addition to retail, in finance banks analyze their past data to build models to use in credit applications, fraud detection, and the stock market. In manufacturing, learning models are used for optimization, control, and troubleshooting. In medicine, learning programs are used for medical diagnosis. In telecommunications, call patterns are analyzed for network optimization and maximizing the quality of service. In science, large amounts of data in physics, astronomy, and biology can only be analyzed fast enough by computers. The World Wide Web is huge; it is constantly growing and searching for relevant information cannot be done manually.

But machine learning is not just a database problem; it is also a part of artificial intelligence. To be intelligent, a system that is in a changing environment should have the ability to learn. If the system can learn and adapt to such changes, the system designer need not foresee and provide solutions for all possible situations.

Machine learning also helps us find solutions to many problems in vision, speech recognition, and robotics. Let us take the example of recognizing faces: This is a task we do effortlessly; every day we recognize family members and friends by looking at their faces or from their photographs, despite differences in pose, lighting, hair style, and so forth. But we do it unconsciously and are unable to explain how we do it. Because we are not able to explain our expertise, we cannot write the computer program. At the same time, we know that a face image is not just a random collection of pixels; a face has structure. It is symmetric. There

are the eyes, the nose, the mouth, located in certain places on the face. Each person's face is a pattern composed of a particular combination of these. By analyzing sample face images of a person, a learning program captures the pattern specific to that person and then recognizes by checking for this pattern in a given image. This is one example of *pattern recognition.*

Machine learning is programming computers to optimize a performance criterion using example data or past experience. We have a model defined up to some parameters, and learning is the execution of a computer program to optimize the parameters of the model using the training data or past experience. The model may be *predictive* to make predictions in the future, or *descriptive* to gain knowledge from data, or both.

Machine learning uses the theory of statistics in building mathematical models, because the core task is making inference from a sample. The role of computer science is twofold: First, in training, we need efficient algorithms to solve the optimization problem, as well as to store and process the massive amount of data we generally have. Second, once a model is learned, its representation and algorithmic solution for inference needs to be efficient as well. In certain applications, the efficiency of the learning or inference algorithm, namely, its space and time complexity, may be as important as its predictive accuracy.

Let us now discuss some example applications in more detail to gain more insight into the types and uses of machine learning.

1.2 Examples of Machine Learning Applications

1.2.1 Learning Associations

In the case of retail—for example, a supermarket chain—one application of machine learning is *basket analysis,* which is finding associations between products bought by customers: If people who buy X typically also buy Y, and if there is a customer who buys X and does not buy Y, he or she is a potential Y customer. Once we find such customers, we can target them for cross-selling.

ASSOCIATION RULE

In finding an *association rule,* we are interested in learning a conditional probability of the form $P(Y|X)$ where Y is the product we would like to condition on X, which is the product or the set of products which we know that the customer has already purchased.

Let us say, going over our data, we calculate that $P(\text{chips}|\text{beer}) = 0.7$. Then, we can define the rule:

70 percent of customers who buy beer also buy chips.

We may want to make a distinction among customers and toward this, estimate $P(Y|X, D)$ where D is the set of customer attributes, for example, gender, age, marital status, and so on, assuming that we have access to this information. If this is a bookseller instead of a supermarket, products can be books or authors. In the case of a Web portal, items correspond to links to Web pages, and we can estimate the links a user is likely to click and use this information to download such pages in advance for faster access.

1.2.2 Classification

A credit is an amount of money loaned by a financial institution, for example, a bank, to be paid back with interest, generally in installments. It is important for the bank to be able to predict in advance the risk associated with a loan, which is the probability that the customer will default and not pay the whole amount back. This is both to make sure that the bank will make a profit and also to not inconvenience a customer with a loan over his or her financial capacity.

In *credit scoring* (Hand 1998), the bank calculates the risk given the amount of credit and the information about the customer. The information about the customer includes data we have access to and is relevant in calculating his or her financial capacity—namely, income, savings, collaterals, profession, age, past financial history, and so forth. The bank has a record of past loans containing such customer data and whether the loan was paid back or not. From this data of particular applications, the aim is to infer a general rule coding the association between a customer's attributes and his risk. That is, the machine learning system fits a model to the past data to be able to calculate the risk for a new application and then decides to accept or refuse it accordingly.

CLASSIFICATION

This is an example of a *classification* problem where there are two classes: low-risk and high-risk customers. The information about a customer makes up the *input* to the classifier whose task is to assign the input to one of the two classes.

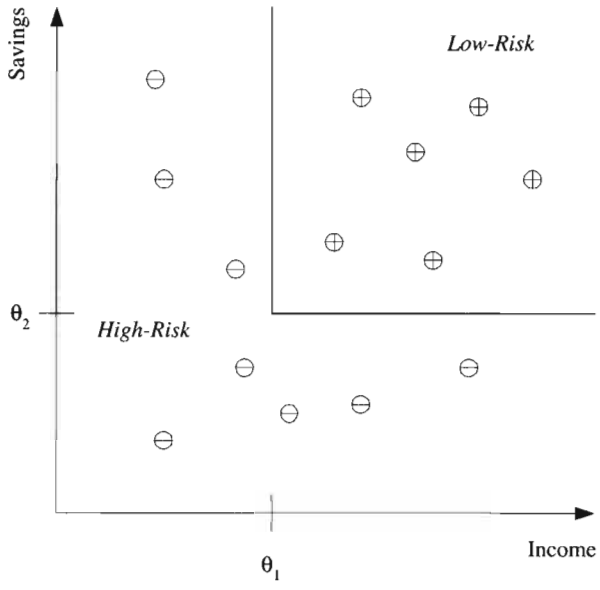

Figure 1.1 Example of a training dataset where each circle corresponds to one data instance with input values in the corresponding axes and its sign indicates the class. For simplicity, only two customer attributes, income and savings, are taken as input and the two classes are low-risk ('+') and high-risk ('−'). An example discriminant that separates the two types of examples is also shown.

After training with the past data, a classification rule learned may be of the form

IF income> θ_1 AND savings> θ_2 THEN low-risk ELSE high-risk

for suitable values of θ_1 and θ_2 (see figure 1.1). This is an example of a *discriminant;* it is a function that separates the examples of different classes.

DISCRIMINANT

PREDICTION

Having a rule like this, the main application is *prediction:* Once we have a rule that fits the past data, if the future is similar to the past, then we can make correct predictions for novel instances. Given a new application with a certain income and savings, we can easily decide whether it is low-risk or high-risk.

In some cases, instead of making a 0/1 (low-risk/high-risk) type decision, we may want to calculate a probability, namely, $P(Y|X)$, where

X are the customer attributes and Y is 0 or 1 respectively for low-risk and high-risk. From this perspective, we can see classification as learning an association from X to Y. Then for a given $X = x$, if we have $P(Y = 1|X = x) = 0.8$, we say that the customer has an 80 percent probability of being high-risk, or equivalently a 20 percent probability of being low-risk. We then decide whether to accept or refuse the loan depending on the possible gain and loss.

PATTERN RECOGNITION

There are many applications of machine learning in *pattern recognition.* One is *optical character recognition,* which is recognizing character codes from their images. This is an example where there are multiple classes, as many as there are characters we would like to recognize. Especially interesting is the case when the characters are handwritten. People have different handwriting styles; characters may be written small or large, slanted, with a pen or pencil, and there are many possible images corresponding to the same character. Though writing is a human invention, we do not have any system that is as accurate as a human reader. We do not have a formal description of 'A' that covers all 'A's and none of the non-'A's. Not having it, we take samples from writers and learn a definition of A-ness from these examples. But though we do not know what it is that makes an image an 'A', we are certain that all those distinct 'A's have something in common, which is what we want to extract from the examples. We know that a character image is not just a collection of random dots; it is a collection of strokes and has a regularity that we can capture by a learning program.

If we are reading a text, one factor we can make use of is the redundancy in human languages. A word is a *sequence* of characters and successive characters are not independent but are constrained by the words of the language. This has the advantage that even if we cannot recognize a character, we can still read t?e word. Such contextual dependencies may also occur in higher levels, between words and sentences, through the syntax and semantics of the language. There are machine learning algorithms to learn sequences and model such dependencies.

In the case of *face recognition,* the input is an image, the classes are people to be recognized, and the learning program should learn to associate the face images to identities. This problem is more difficult than optical character recognition because there are more classes, input image is larger, and a face is three-dimensional and differences in pose and lighting cause significant changes in the image. There may also be occlusion of certain inputs; for example, glasses may hide the eyes and

eyebrows, and a beard may hide the chin.

In *medical diagnosis,* the inputs are the relevant information we have about the patient and the classes are the illnesses. The inputs contain the patient's age, gender, past medical history, and current symptoms. Some tests may not have been applied to the patient, and thus these inputs would be missing. Tests take time, may be costly, and may inconvience the patient so we do not want to apply them unless we believe that they will give us valuable information. In the case of a medical diagnosis, a wrong decision may lead to a wrong or no treatment, and in cases of doubt it is preferable that the classifier reject and defer decision to a human expert.

In *speech recognition,* the input is acoustic and the classes are words that can be uttered. This time the association to be learned is from an acoustic signal to a word of some language. Different people, because of differences in age, gender, or accent, pronounce the same word differently, which makes this task rather difficult. Another difference of speech is that the input is *temporal;* words are uttered in time as a sequence of speech phonemes and some words are longer than others. A recent approach in speech recognition involves the use of lip movements as recorded by a camera as a second source of information in recognizing speech. This requires *sensor fusion,* which is the integration of inputs from different modalities, namely, acoustic and visual.

KNOWLEDGE EXTRACTION

Learning a rule from data also allows *knowledge extraction.* The rule is a simple model that explains the data, and looking at this model we have an explanation about the process underlying the data. For example, once we learn the discriminant separating low-risk and high-risk customers, we have the knowledge of the properties of low-risk customers. We can then use this information to target potential low-risk customers more efficiently, for example, through advertising.

COMPRESSION

Learning also performs *compression* in that by fitting a rule to the data, we get an explanation that is simpler than the data, requiring less memory to store and less computation to process. Once you have the rules of addition, you do not need to remember the sum of every possible pair of numbers.

OUTLIER DETECTION

Another use of machine learning is *outlier detection,* which is finding the instances that do not obey the rule and are exceptions. In this case, after learning the rule, we are not interested in the rule but the exceptions not covered by the rule, which may imply anomalies requiring attention—for example, fraud.

1.2.3 Regression

Let us say we want to have a system that can predict the price of a used car. Inputs are the car attributes—brand, year, engine capacity, milage, and other information—that we believe affect a car's worth. The output is the price of the car. Such problems where the output is a number are *regression* problems.

REGRESSION

Let X denote the car attributes and Y be the price of the car. Again surveying the past transactions, we can collect a training data and the machine learning program fits a function to this data to learn Y as a function of X. An example is given in figure 1.2 where the fitted function is of the form

$$y = wx + w_0$$

for suitable values of w and w_0.

SUPERVISED LEARNING

Both regression and classification are *supervised learning* problems where there is an input, X, an output, Y, and the task is to learn the mapping from the input to the output. The approach in machine learning is that we assume a model defined up to a set of parameters:

$$y = g(x|\theta)$$

where $g(\cdot)$ is the model and θ are its parameters. Y is a number in regression and is a class code (e.g., 0/1) in the case of classification. $g(\cdot)$ is the regression function or in classification, it is the discriminant function separating the instances of different classes. The machine learning program optimizes the parameters, θ, such that the approximation error is minimized, that is, our estimates are as close as possible to the correct values given in the training set. For example in figure 1.2, the model is linear and w and w_0 are the parameters optimized for best fit to the training data. In cases where the linear model is too restrictive, one can use for example a quadratic

$$y = w_2x^2 + w_1x + w_0$$

or a higher-order polynomial, or any other nonlinear function of the input, this time optimizing its parameters for best fit.

Another example of regression is navigation of a mobile robot, for example, an autonomous car, where the output is the angle by which the steering wheel should be turned at each time, to advance without hitting obstacles and deviating from the route. Inputs in such a case are provided by sensors on the car, for example, a video camera, GPS, and so

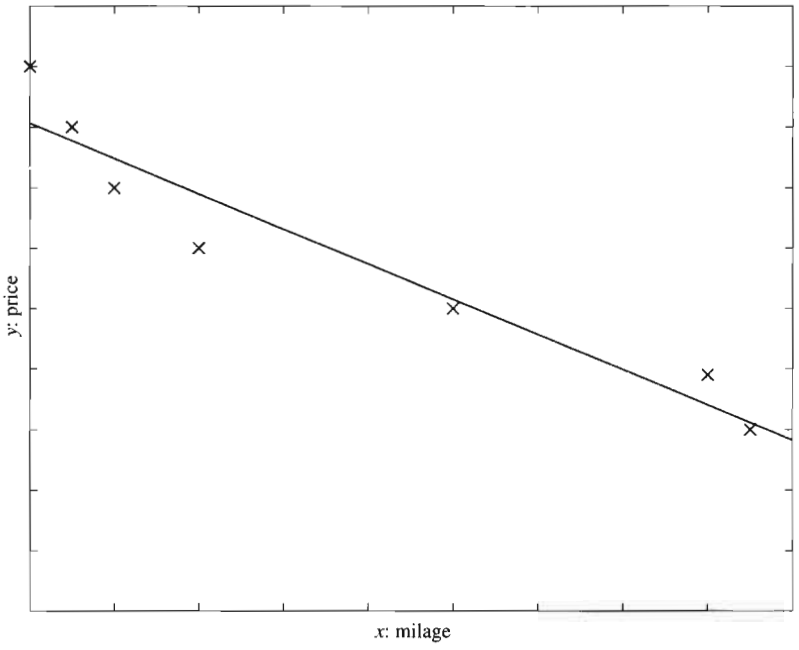

Figure 1.2 A training dataset of used cars and the function fitted. For simplicity, milage is taken as the only input attribute and a linear model is used.

forth. Training data can be collected by monitoring and recording the actions of a human driver.

One can envisage other applications of regression where one is trying to optimize a function.[1] Let us say we want to build a machine that roasts coffee. The machine has many inputs that affect the quality: various settings of temperatures, times, coffee bean type, and so forth. We make a number of experiments and for different settings of these inputs, we measure the quality of the coffee, for example, as consumer satisfaction. To find the optimal setting, we fit a regression model linking these inputs to coffee quality and choose new points to sample near the optimum of the current model to look for a better configuration. We sample these points, check quality, and add these to the data and fit a new model. This is generally called *response surface design.*

1. I would like to thank Michael Jordan for this example.

1.2.4 Unsupervised Learning

In supervised learning, the aim is to learn a mapping from the input to an output whose correct values are provided by a supervisor. In unsupervised learning, there is no such supervisor and we only have input data. The aim is to find the regularities in the input. There is a structure to the input space such that certain patterns occur more often than others, and we want to see what generally happens and what does not. In statistics, this is called *density estimation.*

DENSITY ESTIMATION

CLUSTERING

One method for density estimation is *clustering* where the aim is to find clusters or groupings of input. In the case of a company with a data of past customers, the customer data contains the demographic information as well as the past transactions with the company, and the company may want to see the distribution of the profile of its customers, to see what type of customers frequently occur. In such a case, a clustering model allocates customers similar in their attributes to the same group, providing the company with natural groupings of its customers. Once such groups are found, the company may decide strategies, for example, services and products, specific to different groups. Such a grouping also allows identifying those who are outliers, namely, those who are different from other customers, which may imply a niche in the market that can be further exploited by the company.

An interesting application of clustering is in *image compression.* In this case, the input instances are image pixels represented as RGB values. A clustering program groups pixels with similar colors in the same group, and such groups correspond to the colors occurring frequently in the image. If in an image, there are only shades of a small number of colors and if we code those belonging to the same group with one color, for example, their average, then the image is quantized. Let us say the pixels are 24 bits to represent 16 million colors, but if there are shades of only 64 main colors, for each pixel, we need 6 bits instead of 24. For example, if the scene has various shades of blue in different parts of the image, and if we use the same average blue for all of them, we lose the details in the image but gain space in storage and transmission. Ideally, one would like to identify higher-level regularities by analyzing repeated image patterns, for example, texture, objects, and so forth. This allows a higher-level, simpler, and more useful description of the scene, and for example, achieves better compression than compressing at the pixel level. If we have scanned document pages, we do not have random on/off pix-

els but bitmap images of characters. There is structure in the data, and we make use of this redundancy by finding a shorter description of the data: 16×16 bitmap of 'A' takes 32 bytes; its ASCII code is only 1 byte.

Machine learning methods are also used in *bioinformatics.* DNA in our genome is the "blueprint of life" and is a sequence of bases, namely, A, G, C, and T. RNA is transcribed from DNA, and proteins are translated from the RNA. Proteins are what the living body is and does. Just as a DNA is a sequence of bases, a protein is a sequence of amino acids (as defined by bases). One application area of computer science in molecular biology is *alignment,* which is matching one sequence to another. This is a difficult string matching problem because strings may be quite long, there are many template strings to match against, and there may be deletions, insertions, and substitutions. Clustering is used in learning *motifs,* which are sequences of amino acids that occur repeatedly in proteins. Motifs are of interest because they may correspond to structural or functional elements within the sequences they characterize. The analogy is that if the amino acids are letters and proteins are sentences, motifs are like words, namely, a string of letters with a particular meaning occurring frequently in different sentences.

1.2.5 Reinforcement Learning

In some applications, the output of the system is a sequence of *actions.* In such a case, a single action is not important; what is important is the *policy* that is the sequence of correct actions to reach the goal. There is no such thing as the best action in any intermediate state; an action is good if it is part of a good policy. In such a case, the machine learning program should be able to assess the goodness of policies and learn from past good action sequences to be able to generate a policy. Such learning methods are called *reinforcement learning* algorithms.

REINFORCEMENT LEARNING

A good example is *game playing* where a single move by itself is not that important; it is the sequence of right moves that is good. A move is good if it is part of a good game playing policy. Game playing is an important research area in both artificial intelligence and machine learning. This is because games are easy to describe and at the same time, they are quite difficult to play well. A game like chess has a small number of rules but it is very complex because of the large number of possible moves at each state and the large number of moves that a game contains. Once

we have good algorithms that can learn to play games well, we can also apply them to applications with more evident economic utility.

A robot navigating in an environment in search of a goal location is another application area of reinforcement learning. At any time, the robot can move in one of a number of directions. After a number of trial runs, it should learn the correct sequence of actions to reach to the goal state from an initial state, doing this as quickly as possible and without hitting any of the obstacles. One factor that makes reinforcement learning harder is when the system has unreliable and partial sensory information. For example, a robot equipped with a video camera has incomplete information and thus at any time is in a *partially observable state* and should decide taking into account this uncertainty. A task may also require a concurrent operation of *multiple agents* that should interact and cooperate to accomplish a common goal. An example is a team of robots playing soccer.

1.3 Notes

Evolution is the major force that defines our bodily shape as well as our built-in instincts and reflexes. We also learn to change our behavior during our lifetime. This helps us cope with changes in the environment that cannot be predicted by evolution. Organisms that have a short life in a well-defined environment may have all their behavior built-in, but instead of hardwiring into us all sorts of behavior for any circumstance that we could encounter in our life, evolution gave us a large brain and a mechanism to learn, such that we could update ourselves with experience and adapt to different environments. When we learn the best strategy in a certain situation, that knowledge is stored in our brain, and when the situation arises again, when we re-cognize ("cognize" means to know) the situation, we can recall the suitable strategy and act accordingly. Learning has its limits though; there may be things that we can never learn with the limited capacity of our brains, just like we can never "learn" to grow a third arm, or an eye on the back of our head, even if either would be useful. See Leahey and Harris 1997 for learning and cognition from the point of view of psychology. Note that unlike in psychology, cognitive science, or neuroscience, our aim in machine learning is not to understand the processes underlying learning in humans and animals, but to build useful systems, as in any domain of engineering.

Almost all of science is fitting models to data. Scientists design experiments and make observations and collect data. They then try to extract knowledge by finding out simple models that explain the data they observed. This is called *induction* and is the process of extracting general rules from a set of particular cases.

We are now at a point that such analysis of data can no longer be done by people, both because the amount of data is huge and because people who can do such analysis are rare and manual analysis is costly. There is thus a growing interest in computer models that can analyze data and extract information automatically from them, that is, learn.

The methods we are going to discuss in the coming chapters have their origins in different scientific domains. Sometimes the same algorithm was independently invented in more than one field, following a different historical path.

In statistics, going from particular observations to general descriptions is called *inference* and learning is called *estimation.* Classification is called *discriminant analysis* in statistics (McLachlan 1992; Hastie, Tibshirani, and Friedman 2001). Before computers were cheap and abundant, statisticians could only work with small samples. Statisticians, being mathematicians, worked mostly with simple parametric models that could be analyzed mathematically. In engineering, classification is called *pattern recognition* and the approach is nonparametric and much more empirical (Duda, Hart, and Stork 2001; Webb 1999). Machine learning is related to *artificial intelligence* (Russell and Norvig 1995) because an intelligent system should be able to adapt to changes in its environment. Application areas like vision, speech, and robotics are also tasks that are best learned from sample data. In electrical engineering, research in *signal processing* resulted in adaptive computer vision and speech programs. Among these, the development of *hidden Markov models* (HMM) for speech recognition is especially important.

In the late 1980s with advances in VLSI technology and the possibility of building parallel hardware containing thousands of processors, the field of *artificial neural networks* was reinvented as a possible theory to distribute computation over a large number of processing units (Bishop, 1995). Over time, it has been realized in the neural network community that most neural network learning algorithms have their basis in statistics—for example, the multilayer perceptron is another class of nonparametric estimator—and claims of brain-like computation have started to fade.

Data mining is the name coined in the business world for the application of machine learning algorithms to large amounts of data (Weiss and Indurkhya 1998). In computer science, it is also called *knowledge discovery in databases* (KDD).

Research in these different communities (statistics, pattern recognition, neural networks, signal processing, control, artificial intelligence, and data mining) followed different paths in the past with different emphases. In this book, the aim is to incorporate these emphases together to give a unified treatment of the problems and the proposed solutions to them.

1.4 Relevant Resources

The latest research on machine learning is distributed over journals and conferences from different fields. Dedicated journals are *Machine Learning* and *Journal of Machine Learning Research.* Journals with a neural network emphasis are *Neural Computation, Neural Networks,* and the *IEEE Transactions on Neural Networks.* Statistics journals like *Annals of Statistics* and *Journal of the American Statistical Association* also publish machine learning papers. *IEEE Transactions on Pattern Analysis and Machine Intelligence* is another source.

Journals on artificial intelligence, pattern recognition, fuzzy logic, and signal processing also contain machine learning papers. Journals with an emphasis on data mining are *Data Mining and Knowledge Discovery, IEEE Transactions on Knowledge and Data Engineering,* and *ACM Special Interest Group on Knowledge Discovery and Data Mining Explorations Journal.*

The major conferences on machine learning are *Neural Information Processing Systems* (NIPS), *Uncertainty in Artificial Intelligence* (UAI), *International Conference on Machine Learning* (ICML), *European Conference on Machine Learning* (ECML), and *Computational Learning Theory* (COLT). *International Joint Conference on Artificial Intelligence* (IJCAI), as well as conferences on neural networks, pattern recognition, fuzzy logic, and genetic algorithms, have sessions on machine learning and conferences on application areas like computer vision, speech technology, robotics, and data mining.

There are a number of dataset repositories on the Internet that are used frequently by machine learning researchers for benchmarking purposes:

- *UCI Repository* for machine learning is the most popular repository: http://www.ics.uci.edu/~mlearn/MLRepository.html
- *UCI KDD Archive:* http://kdd.ics.uci.edu/summary.data.application.html
- *Statlib:* http://lib.stat.cmu.edu
- *Delve:* http://www.cs.utoronto.ca/~delve/

Most recent papers by machine learning researchers are accessible over the Internet, and a good place to start searching is the NEC Research Index at http://citeseer.nj.nec.com/cs

1.5 Exercises

1. Imagine you have two possibilities: You can fax a document, that is, send the image, or you can use an optical character reader (OCR) and send the text file. Discuss the advantage and disadvantages of the two approaches in a comparative manner. When would one be preferable over the other?
2. Let us say we are building an OCR and for each character, we store the bitmap of that character as a template that we match with the read character pixel by pixel. Explain when such a system would fail. Why are barcode readers still used?
3. Assume we are given the task to build a system that can distinguish junk e-mail. What is in a junk e-mail that lets us know that it is junk? How can the computer detect junk through a syntactic analysis? What would you like the computer to do if it detects a junk e-mail—delete it automatically, move it to a different file, or just highlight it on the screen?
4. Let us say you are given the task of building an automated taxi. Define the constraints. What are the inputs? What is the output? How can you communicate with the passenger? Do you need to communicate with the other automated taxis, that is, do you need a "language"?
5. In basket analysis, we want to find the dependence between two items X and Y. Given a database of customer transactions, how can you find these dependencies? How would you generalize this to more than two items?
6. How can you predict the next command to be typed by the user? Or the next page to be downloaded over the Web? When would such a prediction be useful? When would it be annoying?

2 *Supervised Learning*

We discuss supervised learning starting from the simplest case, which is learning a class from its positive and negative examples. We generalize and discuss the case of multiple classes, then regression, where the outputs are continuous.

2.1 Learning a Class from Examples

LET US say we want to learn the *class*, C, of a "family car." We have a set of examples of cars, and we have a group of people that we survey to whom we show these cars. The people look at the cars we show them and label them; the cars that they believe are family cars are *positive examples* and the other cars are *negative examples.* Class learning is finding a description that is shared by all positive examples and none of the negative examples. Doing this, we can make a prediction: Given a car that we have not seen before, by checking with the description learned, we will be able to say whether it is a family car or not. Or we can do knowledge extraction: This study may be sponsored by a car company, and the aim may be to understand what people expect from a family car.

POSITIVE EXAMPLES
NEGATIVE EXAMPLES

After some discussions with experts in the field, let us say that we reach the conclusion that among all features a car may have, the features that separate a family car from other cars are the price and engine power. These two attributes are the *inputs* to the class recognizer. Note that when we decide on this particular *input representation,* we are ignoring various other attributes as irrelevant. Though one may think of other attributes such as seating capacity and color that might be important for distinguishing among car types, we will consider only price and engine power to keep this example simple.

INPUT REPRESENTATION

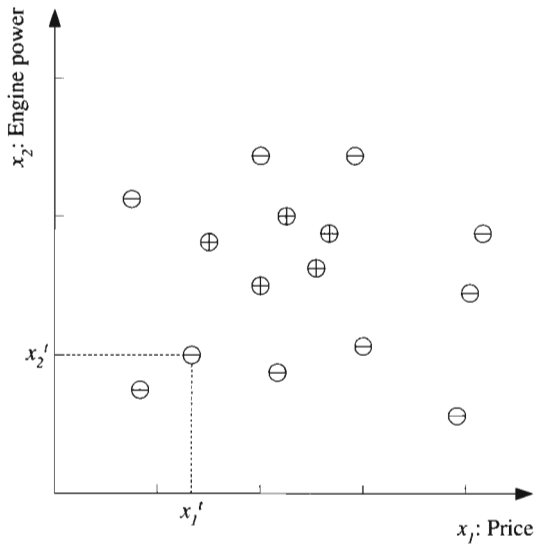

Figure 2.1 Training set for the class of a "family car." Each data point corresponds to one example car and the coordinates of the point indicate the price and engine power of that car. '+' denotes a positive example of the class (a family car), and '−' denotes a negative example (not a family car); it is another type of car.

Let us denote price as the first input attribute x_1 (e.g., in U.S. dollars) and engine power as the second attribute x_2 (e.g., engine volume in cubic centimeters). Thus we represent each car using two numeric values

$$\mathbf{x} = \begin{bmatrix} x_1 \\ x_2 \end{bmatrix} \tag{2.1}$$

and its label denotes its type

$$r = \begin{cases} 1 & \text{if } \mathbf{x} \text{ is a positive example} \\ 0 & \text{if } \mathbf{x} \text{ is a negative example} \end{cases} \tag{2.2}$$

Each car is represented by such an ordered pair $(\mathbf{x}, r)$ and the training set contains N such examples

$$\mathcal{X} = \{\mathbf{x}^t, r^t\}_{t=1}^N \tag{2.3}$$

where t indexes different examples in the set; it does not represent time or any such order.

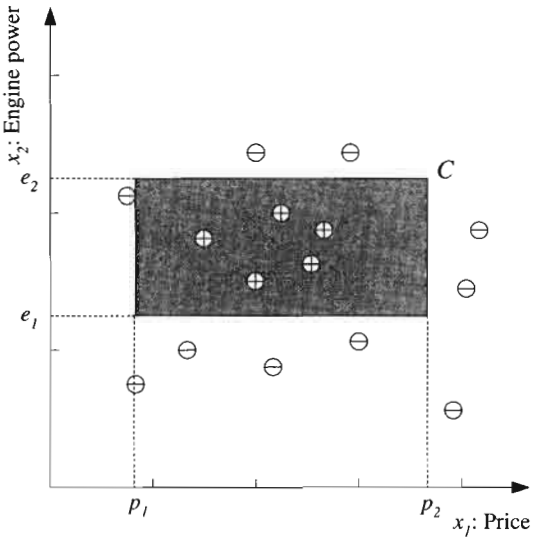

Figure 2.2 Example of a hypothesis class. The class of family car is a rectangle in the price-engine power space.

Our training data can now be plotted in the two-dimensional (x_1, x_2) space where each instance t is a data point at coordinates (x_1^t, x_2^t) and its type, namely, positive versus negative, is given by r^t (see figure 2.1).

After further discussions with the expert and the analysis of the data, we may have reason to believe that for a car to be a family car, its price and engine power should be in a certain range

$$(p_1 \leq \text{price} \leq p_2) \text{ AND } (e_1 \leq \text{engine power} \leq e_2) \tag{2.4}$$

for suitable values of p_1, p_2, e_1, and e_2. Equation 2.4 thus assumes C to be a rectangle in the price-engine power space (see figure 2.2).

HYPOTHESIS CLASS

Equation 2.4 fixes $\mathcal{H}$, the *hypothesis class* from which we believe C is drawn, namely, the set of rectangles. The learning algorithm then should find a particular *hypothesis*, $h \in \mathcal{H}$, to approximate C as closely as possible.

HYPOTHESIS

Though the expert defines this hypothesis class, he cannot say what the values of the parameters are; that is, though we choose $\mathcal{H}$, we do

not know which particular $h \in \mathcal{H}$ is equal, or closest, to C. But once we restrict our attention to this hypothesis class, learning the class reduces to the easier problem of finding the four parameters that define h.

The aim is to find $h \in \mathcal{H}$ that is as similar as possible to C. Let us say the hypothesis h makes a prediction for an instance $\mathbf{x}$ such that

$$h(\mathbf{x}) = \begin{cases} 1 & \text{if } h \text{ classifies } \mathbf{x} \text{ as a positive example} \\ 0 & \text{if } h \text{ classifies } \mathbf{x} \text{ as a negative example} \end{cases} \tag{2.5}$$

In real life we do not know $C(\mathbf{x})$, so we cannot evaluate how well $h(\mathbf{x})$ matches $C(\mathbf{x})$. What we have is a training set $\mathcal{X}$, which is a small subset of the set of all possible $\mathbf{x}$. The *empirical error* is the proportion of training instances where *predictions* of h do not match the *required values* given in $\mathcal{X}$. The error of hypothesis h given the training set $\mathcal{X}$ is

EMPIRICAL ERROR

$$E(h|\mathcal{X}) = \sum_{t=1}^{N} 1(h(\mathbf{x}^t) \neq r^t) \tag{2.6}$$

where $1(a \neq b)$ is 1 if $a \neq b$ and is 0 if $a = b$ (see figure 2.3).

In our example, the hypothesis class $\mathcal{H}$ is the set of all possible rectangles. Each quadruple $(p_1^h, p_2^h, e_1^h, e_2^h)$ defines one hypothesis, h, from $\mathcal{H}$, and we need to choose the best one, or in other words, we need to find the values of these four parameters given the training set, to include all the positive examples and none of the negative examples. Note that if x_1 and x_2 are real-valued, there are infinitely many such h for which this is satisfied, namely, for which the error, E, is zero, but given a future example somewhere close to the boundary between positive and negative examples, different candidate hypotheses may make different predictions. This is the problem of *generalization*—that is, how well our hypothesis will correctly classify future examples that are not part of the training set.

GENERALIZATION

MOST SPECIFIC HYPOTHESIS

One possibility is to find the *most specific hypothesis, S*, that is the tightest rectangle that includes all the positive examples and none of the negative examples (see figure 2.4). This gives us one hypothesis, $h = S$, as our induced class. Note that the actual class C may be larger than S but is never smaller. The *most general hypothesis, G*, is the largest rectangle we can draw that includes all the positive examples and none of the negative examples (figure 2.4). Any $h \in \mathcal{H}$ between S and G is a valid hypothesis with no error, said to be *consistent* with the training set, and such h make up the *version space.*

MOST GENERAL HYPOTHESIS

VERSION SPACE

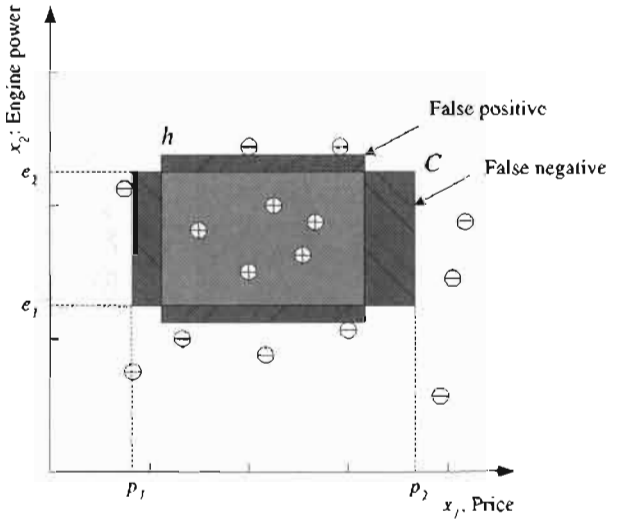

Figure 2.3 C is the actual class and h is our induced hypothesis. The point where C is 1 but h is 0 is a false negative, and the point where C is 0 but h is 1 is a false positive. Other points, namely true positives and true negatives, are correctly classified.

Given $\mathcal{X}$, we can find S, or G, or maybe an average of them (why?), or any h from the version space and use it as our hypothesis, h. Given another training set, the parameters and thus the learned hypothesis, h, can be different.

As another possibility, we can say that any instance covered by S is positive, any instance not covered by G is negative, and any other instance (between S and G) is a case of *doubt*, which we cannot label with certainty due to lack of data. In such a case, the system *rejects* the instance and defers the decision to a human expert.

DOUBT

Here, we assume that $\mathcal{H}$ includes C; that is, there exists $h \in \mathcal{H}$, such that $E(h|\mathcal{X})$ is zero. Given a hypothesis class $\mathcal{H}$, it may be the case that we cannot learn C; that is, there exists no $h \in \mathcal{H}$ for which the error is zero. Thus, in any application, we need to make sure that $\mathcal{H}$ is flexible enough, or has enough "capacity," to learn C.

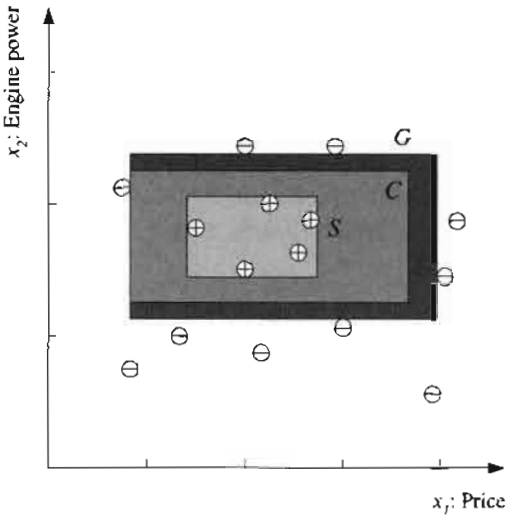

Figure 2.4 S is the most specific hypothesis and G is the most general hypothesis.

2.2 Vapnik-Chervonenkis (VC) Dimension

Let us say we have a dataset containing N points. These N points can be labeled in 2^N ways as positive and negative. Therefore, 2^N different learning problems can be defined by N data points. If for any of these problems, we can find a hypothesis $h \in \mathcal{H}$ that separates the positive examples from the negative, then we say $\mathcal{H}$ *shatters* N points. That is, any learning problem definable by N examples can be learned with no error by a hypothesis drawn from $\mathcal{H}$. The maximum number of points that can be shattered by $\mathcal{H}$ is called the *Vapnik-Chervonenkis* (VC) *dimension* of $\mathcal{H}$, is denoted as $VC(\mathcal{H})$, and measures the *capacity* of the hypothesis class $\mathcal{H}$.

VC DIMENSION

In figure 2.5, we see that an axis-aligned rectangle can shatter four points in two dimensions. Then $VC(\mathcal{H})$, when $\mathcal{H}$ is the hypothesis class of axis-aligned rectangles in two dimensions, is four. In calculating the VC dimension, it is enough that we find four points that can be shattered; it is not necessary that we be able to shatter *any* four points in two di-

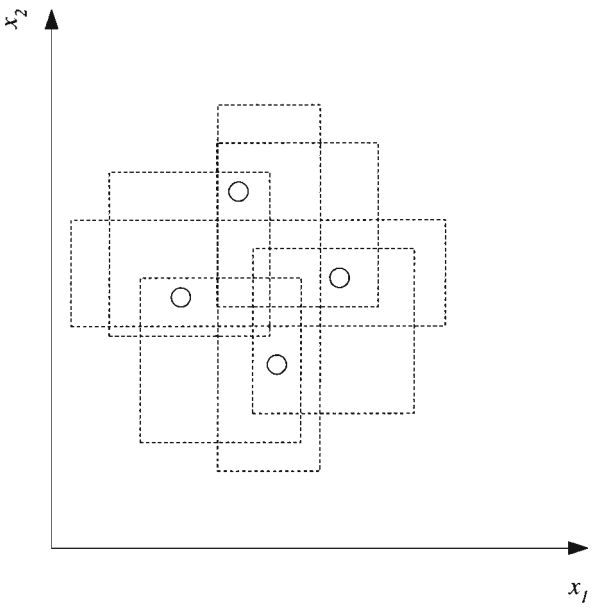

Figure 2.5 An axis-aligned rectangle can shatter four points. Only rectangles covering two points are shown.

mensions. For example, four points placed on a line cannot be shattered by rectangles. However, we cannot place five points in two dimensions *anywhere* such that a rectangle can separate the positive and negative examples for all possible labelings.

VC dimension may seem pessimistic. It tells us that using a rectangle as our hypothesis class, we can learn only datasets containing four points and not more. A learning algorithm that can learn datasets of four points is not very useful. However, this is because the VC dimension is independent of the probability distribution from which instances are drawn. In real life, the world is smoothly changing, instances close by most of the time have the same labels, and we need not worry about *all possible labelings.* There are a lot of datasets containing many more data points than four that are learnable by our hypothesis class (figure 2.1). So even hypothesis classes with small VC dimensions are applicable and are preferred over those with large VC dimensions, for example, a lookup table that has infinite VC dimension.

2.3 Probably Approximately Correct (PAC) Learning

Using the tightest rectangle, S, as our hypothesis, we would like to find how many examples we need. We would like our hypothesis to be approximately correct, namely, that the error probability be bounded by some value. We also would like to be confident in our hypothesis in that we want to know that our hypothesis will be correct most of the time (if not always); so we want to be probably correct as well (by a probability we can specify).

PAC LEARNING

In *Probably Approximately Correct* (PAC) *learning,* given a class, C, and examples drawn from some unknown but fixed probability distribution, $p(x)$, we want to find the number of examples, N, such that with probability at least $1 - \delta$, the hypothesis h has error at most ϵ, for arbitrary $\delta \leq 1/2$ and $\epsilon > 0$

$$P\{C\Delta h \leq \epsilon\} \geq 1 - \delta$$

where $C\Delta h$ is the region of difference between C and h.

In our case, because S is the tightest possible rectangle, the error region between C and $h = S$ is the sum of four rectangular strips (see figure 2.6). We would like to make sure that the probability of a positive example falling in here (and causing an error) is at most ϵ. For any of these strips, if we can guarantee that the probability is upper bounded by $\epsilon/4$, the error is at most $4(\epsilon/4) = \epsilon$. Note that we count the overlaps in the corners twice, and the total actual error in this case is less than $4(\epsilon/4)$. The probability that a randomly drawn example misses this strip is $1 - \epsilon/4$. The probability that all N independent draws miss the strip is $(1 - \epsilon/4)^N$, and the probability that all N independent draws miss any of the four strips is at most $4(1 - \epsilon/4)^N$, which we would like to be at most δ. We have the inequality

$$(1 - x) \leq \exp[-x]$$

So if we choose N and δ such that we have

$$4\exp[-\epsilon N/4] \leq \delta$$

we can also write $4(1 - \epsilon/4)^N \leq \delta$. Dividing both sides by 4, taking (natural) log and rearranging terms, we have

$$N \geq (4/\epsilon)\log(4/\delta) \tag{2.7}$$

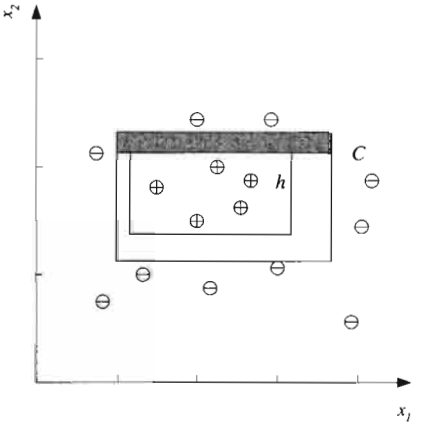

Figure 2.6 The difference between h and C is the sum of four rectangular strips, one of which is shaded.

Therefore, provided that we take at least $(4/\epsilon)\log(4/\delta)$ independent examples from C and use the tightest rectangle as our hypothesis h, with *confidence probability* at least $1 - \delta$, a given point will be misclassified with *error probability* at most ϵ. We can have arbitrary large confidence by decreasing δ and arbitrary small error by decreasing ϵ, and we see in equation 2.7 that the number of examples is a slowly growing function of $1/\epsilon$ and $1/\delta$, linear and logarithmic respectively.

2.4 Noise

NOISE *Noise* is any unwanted anomaly in the data and due to noise, the class may be more difficult to learn and zero error may be infeasible with a simple hypothesis class (see figure 2.7). There are several interpretations of noise:

- There may be imprecision in recording the input attributes, which may shift the data points in the input space.
- There may be errors in labeling the data points, which may relabel

positive instances as negative and vice versa. This is sometimes called *teacher noise.*

- There may be additional attributes, which we have not taken into account, that affect the label of an instance. Such attributes may be *hidden* or *latent* in that they may be unobservable. The effect of these neglected attributes is thus modeled as a random component and is included in "noise."

As can be seen in figure 2.7, when there is noise, there is not a simple boundary between the positive and negative instances and to separate them, one needs a complicated hypothesis that corresponds to a hypothesis class with larger capacity. A rectangle can be defined by four numbers, but to define a more complicated shape one needs a more complex model with a much larger number of parameters. With a complex model, one can make a perfect fit to the data and attain zero error; see the wiggly shape in figure 2.7. Another possibility is to keep the model simple and allow some error; see the rectangle in figure 2.7.

Using the simple rectangle (unless its training error is much bigger) makes more sense because of the following:

1. It is a simple model to use. It is easy to check whether a point is inside or outside a rectangle and we can easily check, for a future data instance, whether it is a positive or a negative instance.

2. It is a simple model to train and has fewer parameters. It is easier to find the corner values of a rectangle than the control points of an arbitrary shape. With a small training set when the training instances differ a little bit, we expect the simpler model to change less than a complex model: A simple model is thus said to have less *variance.* On the other hand, a too simple model assumes more, is more rigid, and may fail if indeed the underlying class is not that simple: A simpler model has more *bias.* Finding the optimal model corresponds to minimizing both the bias and the variance.

3. It is a simple model to explain. A rectangle simply corresponds to defining intervals on the two attributes. By learning a simple model, we can extract information from the raw data given in the training set.

4. If indeed there is mislabeling or noise in input and the actual class is really a simple model like the rectangle, then the simple rectangle, because it has less variance and is less affected by single instances, will

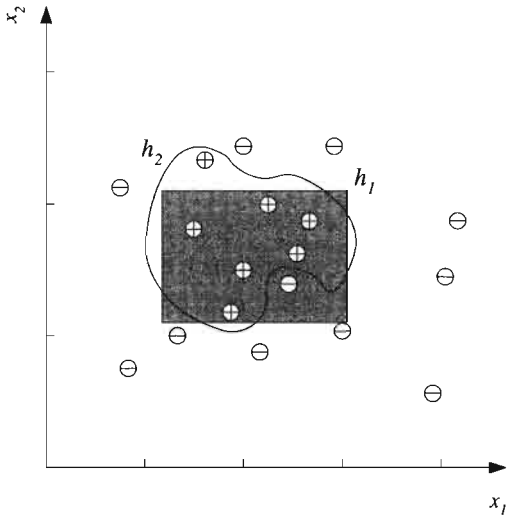

Figure 2.7 When there is noise, there is not a simple boundary between the positive and negative instances, and zero misclassification error may not be possible with a simple hypothesis. A rectangle is a simple hypothesis with four parameters defining the corners. An arbitrary closed form can be drawn by piecewise functions with a larger number of control points.

OCCAM'S RAZOR

be a better discriminator than the wiggly shape, although the simple one may make more errors on the training set. We say that a simple (but not too simple) model would generalize better than a complex model. This principle is known as *Occam's razor,* which states that *simpler explanations are more plausible* and any unnecessary complexity should be shaved off.

2.5 Learning Multiple Classes

In our example of learning a family car, we have positive examples belonging to the class family car and the negative examples belonging to all other cars. This is a *two-class* problem. In the general case, we have K

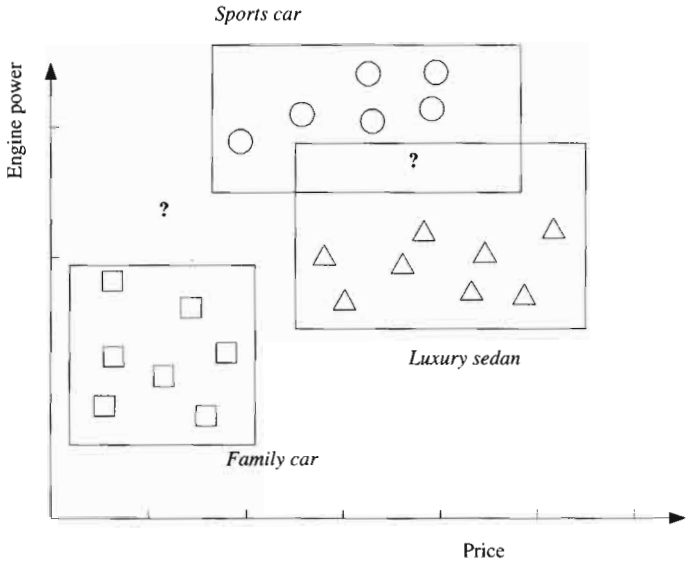

Figure 2.8 There are three classes: family car, sports car, and luxury sedan. There are three hypotheses induced, each one covering the instances of one class and leaving outside the instances of the other two classes. '?' are reject regions where no, or more than one, class is chosen.

classes denoted as $C_i, i = 1, \ldots, K$, and an input instance belongs to one and exactly one of them. The training set is now of the form

$$\mathcal{X} = \{\boldsymbol{x}^t, \boldsymbol{r}^t\}_{t=1}^N$$

where $\boldsymbol{r}$ has K dimensions and

$$r_i^t = \begin{cases} 1 & \text{if } \boldsymbol{x}^t \in C_i \\ 0 & \text{if } \boldsymbol{x}^t \in C_j, j \neq i \end{cases} \tag{2.8}$$

An example is given in figure 2.8 with instances from three classes: family car, sports car, and luxury sedan.

In machine learning for classification, we would like to learn the boundary separating the instances of one class from the instances of all other classes. Thus we view a K-class classification problem as K two-class problems. The training examples belonging to C_i are the positive instances of hypothesis h_i and the examples of all other classes are the

negative instances of h_i. Thus in a K-class problem, we have K hypotheses to learn such that

$$h_i(\boldsymbol{x}^t) = \begin{cases} 1 & \text{if } \boldsymbol{x}^t \in C_i \\ 0 & \text{if } \boldsymbol{x}^t \in C_j, j \neq i \end{cases} \tag{2.9}$$

For a given $\boldsymbol{x}$, ideally only one of $h_i(\boldsymbol{x}), i = 1, \ldots, K$ is 1 and we can choose a class. But when no, or two or more, $h_i(\boldsymbol{x})$ is 1, we cannot choose a class, and this is the case of *doubt* and the classifier *rejects* such cases.

REJECT

In our example of learning a family car, we used only one hypothesis and only modeled the positive examples. Any negative example outside is not a family car. Alternatively, sometimes we may prefer to build two hypotheses, one for the positive and the other for the negative instances. This assumes a structure also for the negative instances that can be covered by another hypothesis. Separating family cars from sports cars is such a problem; each class has a structure of its own. The advantage is that if the input is a luxury sedan, we can have both hypotheses decide negative and reject the input.

2.6 Regression

In classification, given an input, the output that is generated is Boolean; it is a yes/no answer. When the output is a numeric value, what we would like to learn is not a class, $C(\boldsymbol{x}) \in \{0, 1\}$, but is a continuous function. In machine learning, the function is not known but we have a training set of examples drawn from it

$$\mathcal{X} = \{\boldsymbol{x}^t, r^t\}_{t=1}^N$$

INTERPOLATION

where $r^t \in \Re$. If there is no noise, the task is *interpolation*. We would like to find the function $f(x)$ that passes through these points such that we have

$$r^t = f(\boldsymbol{x}^t)$$

In *polynomial interpolation*, given N points, we find the $(N-1)$st degree polynomial that we can use to predict the output for any $\boldsymbol{x}$. This is called *extrapolation* if $\boldsymbol{x}$ is outside of the range of $\boldsymbol{x}^t$ in the training set. In time-series prediction, for example, we have data up to the present and we want to predict the value for the future. In *regression*, there is noise added to the output of the unknown function

EXTRAPOLATION

REGRESSION

$$r^t = f(\boldsymbol{x}^t) + \epsilon \tag{2.10}$$

where $f(\boldsymbol{x}) \in \Re$ is the unknown function and ϵ is random noise. The explanation for noise is that there are extra *hidden* variables that we cannot observe

$$r^t = f^*(\boldsymbol{x}^t, \boldsymbol{z}^t) \tag{2.11}$$

where $\boldsymbol{z}^t$ denote those hidden variables. We would like to approximate the output by our model $g(\boldsymbol{x})$. The empirical error on the training set $\mathcal{X}$ is

$$E(g|\mathcal{X}) = \frac{1}{N}\sum_{t=1}^{N}[r^t - g(\boldsymbol{x}^t)]^2 \tag{2.12}$$

Because r and $g(\boldsymbol{x})$ are numeric quantities, for example, $\in \Re$, there is an ordering defined on their values and we can define a *distance* between values, as the square of the difference, which gives us more information than equal/not equal, as used in classification. The square of the difference is one error function that can be used; another is the absolute value of the difference. We will see other examples in the coming chapters.

Our aim is to find $g(\cdot)$ that minimizes the empirical error. Again our approach is the same; we assume a hypothesis class for $g(\cdot)$ with a small set of parameters. If we assume that $g(\boldsymbol{x})$ is linear, we have

$$g(\boldsymbol{x}) = w_1 x_1 + \cdots + w_d x_d + w_0 = \sum_{j=1}^{d} w_j x_j + w_0 \tag{2.13}$$

Let us now go back to our example in section 1.2.3 where we estimated the price of a used car. There we used a single input linear model

$$g(x) = w_1 x + w_0 \tag{2.14}$$

where w_1 and w_0 are the parameters to learn from data. The w_1 and w_0 values should minimize

$$E(w_1, w_0|\mathcal{X}) = \sum_{t=1}^{N}[r^t - (w_1 x + w_0)]^2 \tag{2.15}$$

Its minimum point can be calculated by taking the partial derivatives of E with respect to w_1 and w_0, setting them equal to 0, and solving for the two unknowns:

$$\begin{aligned} w_1 &= \frac{\sum_t x^t r^t - \overline{xr}N}{\sum_t (x^t)^2 - N\overline{x}^2} \\ w_0 &= \overline{r} - w_1 \overline{x} \end{aligned} \tag{2.16}$$

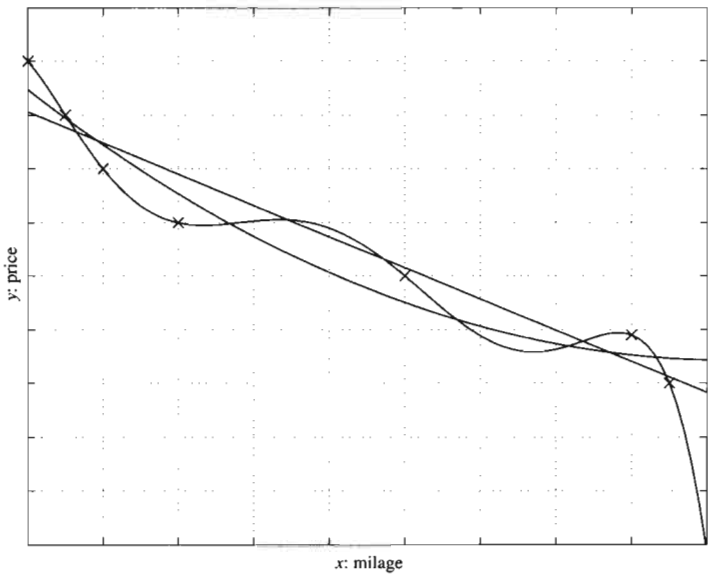

Figure 2.9 Linear, second-order, and sixth-order polynomials are fitted to the same set of points. The highest order gives a perfect fit but given this much data, it is very unlikely that the real curve is so shaped. The second order seems better than the linear fit in capturing the trend in the training data.

where $\overline{x} = \sum_t x^t/N$, $\overline{r} = \sum_t r^t/N$. The line found is shown in figure 1.2.

If the linear model is too simple, it is too constrained and incurs a large approximation error, and in such a case, the output may be taken as a higher-order function of the input, for example, quadratic

$$g(x) = w_2x^2 + w_1x + w_0 \tag{2.17}$$

where similarly we have an analytical solution for the parameters. When the order of the polynomial is increased, the error on the training data decreases. But a high-order polynomial follows individual examples closely instead of capturing the general trend (see the sixth-order polynomial in figure 2.9), so we should be careful when fine-tuning the model complexity to the complexity of the function underlying the data.

2.7 Model Selection and Generalization

Let us start with the case of learning a Boolean function from examples. In a Boolean function, all inputs and the output are binary. There are 2^d possible ways to write d binary values and therefore, with d inputs, the training set has at most 2^d examples. As shown in table 2.1, each of these can be labeled as 0 or 1, and therefore, there are 2^{2^d} possible Boolean functions of d inputs.

Each distinct training example removes half the hypotheses, namely, those whose guesses are wrong. For example, let us say we have $x_1 = 0$, $x_2 = 1$ and the output is 0; this removes $h_5, h_6, h_7, h_8, h_{13}, h_{14}, h_{15}, h_{16}$. This is one way to see learning; as we see more training examples, we remove those hypotheses that are not consistent with the training data. In the case of a Boolean function, to end up with a single hypothesis we need to see *all* 2^d training examples. If the training set we are given contains only a small subset of all possible instances, as it generally does—that is, if we know what the output should be for only a small percentage of the cases—the solution is not unique. After seeing N example cases, there remain 2^{2^d-N} possible functions. This is an example of an *ill-posed problem* where the data by itself is not sufficient to find a unique solution.

ILL-POSED PROBLEM

The same problem also exists in other learning applications, in classification, and in regression. As we see more training examples, we know more about the underlying function, and we carve out more hypotheses that are inconsistent from the hypothesis class, but we still are left with many consistent hypotheses.

So because learning is ill-posed, and data by itself is not sufficient to find the solution, we should make some extra assumptions to have a unique solution with the data we have. The set of assumptions we make to have learning possible is called the *inductive bias* of the learning algorithm. One way we introduce inductive bias is when we assume a hypothesis class. In learning the class of family car, there are infinitely many ways of separating the positive examples from the negative examples. Assuming the shape of a rectangle is one inductive bias, and then the tightest fitting rectangle, for example, is another inductive bias. In linear regression, assuming a linear function is an inductive bias.

INDUCTIVE BIAS

But we know that each hypothesis class has a certain capacity and can learn only certain functions. The class of functions that can be learned can be extended by using a hypothesis class with larger capacity, containing more complex hypotheses. For example, the hypothesis class that is

Table 2.1 With two inputs, there are four possible cases and sixteen possible Boolean functions.

x_1	x_2	h_1	h_2	h_3	h_4	h_5	h_6	h_7	h_8	h_9	h_{10}	h_{11}	h_{12}	h_{13}	h_{14}	h_{15}	h_{16}
0	0	0	0	0	0	0	0	0	0	1	1	1	1	1	1	1	1
0	1	0	0	0	0	1	1	1	1	0	0	0	0	1	1	1	1
1	0	0	0	1	1	0	0	1	1	0	0	1	1	0	0	1	1
1	1	0	1	0	1	0	1	0	1	0	1	0	1	0	1	0	1

a union of two nonoverlapping rectangles has higher capacity, but its hypotheses are more complex. Similarly in regression, as we increase the order of the polynomial, the capacity and complexity increase. The question now is to decide where to stop.

MODEL SELECTION

Thus learning is not possible without inductive bias, and now the question is how to choose the right bias. This is called *model selection.* In answering this question, we should remember that the aim of machine learning is rarely to replicate the training data but the prediction for new cases. That is we would like to be able to generate the right output for an input instance outside the training set, one for which the correct output is not given in the training set. How well a model trained on the training set predicts the right output for new instances is called *generalization.*

GENERALIZATION

UNDERFITTING

For best generalization, we should match the complexity of the hypothesis with the complexity of the function underlying the data. If the hypothesis is less complex than the function, we have *underfitting,* for example, when trying to fit a line to data sampled from a third-order polynomial. In such a case, as we increase the complexity, both the training error and the validation error decrease. But if we have a hypothesis that is too complex, the data is not enough to constrain it and we may end up with a bad hypothesis, for example, when fitting two rectangles to data sampled from one rectangle. Or if there is noise, an overcomplex hypothesis may learn not only the underlying function but also the noise in the data and may make a bad fit, for example, when fitting a sixth-order polynomial to noisy data sampled from a third-order polynomial.

OVERFITTING

This is called *overfitting.* In such a case, having more training data helps but only up to a certain point.

TRIPLE TRADE-OFF

We can summarize our discussion citing the *triple trade-off* (Dietterich 2003). In all learning algorithms that are trained from example data,

there is a trade-off between three factors:

- the complexity of the hypothesis we fit to data, namely, the capacity of the hypothesis class,
- the amount of training data, and
- the generalization error on new examples.

As the amount of training data increases, the generalization error decreases. As the complexity of the model increases, the generalization error decreases first and then starts to increase. The generalization error of an overcomplex hypothesis can be kept in check by increasing the amount of training data but only up to a point.

We can measure the generalization ability of a hypothesis, namely, the quality of its inductive bias, if we have access to data outside the training set. We simulate this by dividing the training set we have into two parts. We use one part for training (i.e., to find a hypothesis), and the remaining part is called the *validation set* and is used to test the generalization ability. Assuming large enough training and validation sets, the hypothesis that is the most accurate on the validation set is the best one (the one that has the best inductive bias). This process is called *cross-validation.* So, for example, to find the right order in polynomial regression, given a number of candidate polynomials of different orders, we find their coefficients on the training set, calculate their errors on the validation set, and take the one that has the least validation error as the best polynomial.

VALIDATION SET

CROSS-VALIDATION

Note that if we need to report the error to give an idea about the expected error of our best model, we should not use the validation error. We have used the validation set to choose the best model, and it has effectively become a part of the training set. We need a third set, a *test set,* sometimes also called the *publication set,* containing examples not used in training or validation. An analogy from our lives is when we are taking a course: The example problems that the instructor solves in class while teaching a subject form the training set; exam questions are the validation set; and the problems we solve in our later, professional life are the test set.

TEST SET

In chapter 14, we discuss how to assess the error rate of a model and how to choose the better of two models when we do not have large datasets to be easily divided into two or three.

2.8 Dimensions of a Supervised Machine Learning Algorithm

Let us now recapitulate and generalize. We have a sample

$$\mathcal{X} = \{x^t, r^t\}_{t=1}^N \tag{2.18}$$

IID

The sample is *independent and identically distributed* (*iid*); the ordering is not important and all instances are drawn from the same joint distribution $p(x, r)$. t indexes one of the N instances, x^t is the arbitrary dimensional input, and r^t is the associated desired output. r^t is 0/1 for two-class learning, is a K-dimensional binary vector (where exactly one of the dimensions is 1 and all others 0) for $(K > 2)$-class classification, and is a real value in regression.

The aim is to build a good and useful approximation to r^t using the model $g(x^t|\theta)$. In doing this, there are three decisions we must make:

1. *Model* we use in learning, denoted as

   $$g(x|\theta)$$

   where $g(\cdot)$ is the model, x is the input, and θ are the parameters. $g(\cdot)$ defines the hypothesis class, and a particular value of θ instantiates one hypothesis from the hypothesis class. For example, in class learning, we have taken a rectangle as our model whose four coordinates make up θ; in linear regression, the model is the linear function of the input whose slope and intercept are the parameters learned from the data. The model (inductive bias) is fixed by the machine learning system designer based on his or her knowledge of the application. The parameters are tuned by a learning algorithm using the training set, sampled from that application.

2. *Loss function*, $L(\cdot)$, to compute the difference between the desired output, r^t, and our approximation to it, $g(x^t|\theta)$, given the current value of the parameters, θ. The *approximation error,* or *loss,* is the sum of losses over the individual instances

   $$E(\theta|\mathcal{X}) = \sum_t L(r^t, g(x^t|\theta)) \tag{2.19}$$

   In class learning where outputs are 0/1, $L(\cdot)$ checks for equality or not; in regression, because the output is a numeric value, we have ordering information for distance and one possibility is to use the square of the difference.

3. *Optimization procedure* to find θ^* that minimizes the approximation error

$$\theta^* = \arg\min_{\theta} E(\theta|\mathcal{X}) \tag{2.20}$$

where arg min returns the argument that minimizes. In regression, we can solve analytically for the optimum. With more complex models and error functions, we may need to use more complex optimization methods, for example, gradient-based methods, simulated annealing, or genetic algorithms.

For this to work well, the following conditions should be satisfied: First, the hypothesis class of $g(\cdot)$ should be large enough, that is, have enough capacity, to include the unknown function that generated the data that is represented in r^t in a noisy form. Second, there should be enough training data to allow us to pinpoint the correct (or a good enough) hypothesis from the hypothesis class. Third, we should have a good optimization method that finds the correct hypothesis given the training data.

Different machine learning algorithms differ either in the models they assume (their hypothesis class/inductive bias), the loss measures they employ, or the optimization procedure they use. We will see many examples in the coming chapters.

2.9 Notes

Mitchell proposed version spaces and the candidate elimination algorithm to incrementally build S and G as instances are given one by one; see Mitchell 1997 for a recent review. Hirsh (1990) discusses how version spaces can handle the case when instances are perturbed by small amount of noise. In one of the earliest works on machine learning, Winston (1975) proposed the idea of a "near miss." A near miss is a negative example that is very much like a positive example. In our terminology, we see that a near miss would be an instance that falls in the gray area between S and G, and would be more useful for learning, than an ordinary positive or negative example. Related to this idea is *active learning* where the learning algorithm can generate instances itself and ask for them to be labeled, instead of passively being given them (Angluin 1988) (see exercise 6).

VC dimension was proposed by Vapnik and Chervonenkis in the early 1970s. A recent source is Vapnik 1995 where he writes, "Nothing is more practical than a good theory" (p. x), which is as true in machine learning as in any other branch of science. You should not rush to the computer; you can save yourself from hours of useless programming by some thinking, a notebook, and a pencil—you may also need an eraser.

The PAC model was proposed by Valiant (1984). The PAC analysis of learning a rectangle is from Blumer et al. 1989. A good textbook on computational learning theory covering PAC learning and VC dimension is Kearns and Vazirani 1994.

2.10 Exercises

1. Write the computer program that finds S and G from a given training set.
2. Imagine you are given the training instances one at a time, instead of all at once. How can you incrementally adjust S and G in such a case? (Hint: See the candidate elimination algorithm in Mitchell 1997.)
3. Why is it better to use the average of S and G as the final hypothesis?
4. Let us say our hypothesis class is a circle instead of a rectangle. What are the parameters? How can the parameters of a circle hypothesis be calculated in such a case? What if it is an ellipse? Why does it make more sense to use an ellipse instead of a circle? How can you generalize your code to $K > 2$ classes?
5. Imagine our hypothesis is not one rectangle but a union of two (or $m > 1$) rectangles. What is the advantage of such a hypothesis class? Show that any class can be represented by such a hypothesis class with large enough m.
6. If we have a supervisor who can provide us with the label for any $\mathbf{x}$, where should we choose $\mathbf{x}$ to learn with fewer queries?
7. In equation 2.12, we summed up the squares of the differences between the actual value and the estimated value. This error function is the one most frequently used, but it is one of several possible error functions. Because it sums up the squares of the differences, it is not robust to outliers. What would be a better error function to implement *robust regression*?
8. Derive equation 2.16.
9. Assume our hypothesis class is the set of lines, and we use a line to separate the positive and negative examples, instead of bounding the positive examples as in a rectangle, leaving the negatives outside (see figure 2.10). Show that the VC dimension of a line is 3.

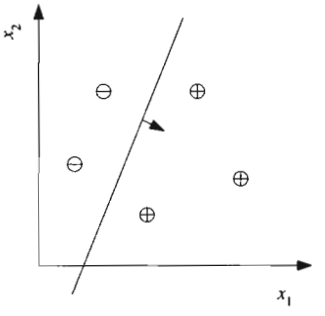

Figure 2.10 A line separating positive and negative instances.

10. Show that the VC dimension of the triangle hypothesis class is 7 in two dimensions. (Hint: For best separation, it is best to place the seven points equidistant on a circle.)

3 *Bayesian Decision Theory*

We discuss probability theory as the framework for making decisions under uncertainty. In classification, Bayes' rule is used to calculate the probabilities of the classes. We generalize to discuss how we can make rational decisions to minimize expected risk. We also introduce Bayesian networks to visually and efficiently represent dependencies among random variables.

3.1 Introduction

PROGRAMMING COMPUTERS to make inference from data is a cross between statistics and computer science, where statisticians provide the mathematical framework of making inference from data and computer scientists work on the efficient hardware and software implementation of the inference methods on computers.

Data comes from a process that is not completely known. This lack of knowledge is indicated by modeling the process as a random process. Maybe the process is actually deterministic, but because we do not have access to complete knowledge about it, we model it as random and use probability theory to analyze it. At this point, it may be a good idea to jump to the appendix and review basic probability theory before continuing with this chapter.

Tossing a coin is a random process because we cannot predict at any toss whether the outcome will be heads or tails—that is why we toss coins, or buy lottery tickets, or get insurance. We can only talk about the probability that the outcome of the next toss will be heads or tails. It may be argued that if we have access to extra knowledge such as the exact composition of the coin, its initial position, the force and its direction

that is applied to the coin when tossing it, where and how it is caught, and so forth, the exact outcome of the toss can be predicted.

UNOBSERVABLE VARIABLES
OBSERVABLE VARIABLE

The extra pieces of knowledge that we do not have access to are named the *unobservable variables.* In the coin tossing example, the only *observable variable* is the outcome of the toss. Denoting the unobservables by $\mathbf{z}$ and the observable as x, in reality we have

$$x = f(\mathbf{z})$$

where $f(\cdot)$ is the deterministic function that defines the outcome from the unobservable pieces of knowledge. Because we cannot model the process this way, we define the outcome X as a random variable drawn from a probability distribution $P(X = x)$ that specifies the process.

The outcome of tossing a coin is heads or tails, and we define a random variable that takes one of two values. Let us say $X = 1$ denotes that the outcome of a toss is heads and $X = 0$ denotes tails. Such X are Bernoulli-distributed where the parameter of the distribution p_o is the probability that the outcome is heads.

$$P(X = 1) = p_o \text{ and } P(X = 0) = 1 - P(X = 1) = 1 - p_o$$

Assume that we are asked to predict the outcome of the next toss. If we know p_o, our prediction will be heads if $p_o > 0.5$ and tails otherwise. This is because if we choose the more probable case, the probability of error, which is 1 minus the probability of our choice, will be minimum. If this is a fair coin with $p_o = 0.5$, we have no better means of prediction than choosing heads all the time or tossing a fair coin ourselves!

SAMPLE

If we do not know $P(X)$ and want to estimate this from a given sample, then we are in the realm of statistics. We have a *sample,* $\mathcal{X}$, containing examples drawn from the probability distribution of the observables x^t, denoted as $p(x)$. The aim is to build an approximator to it, $\hat{p}(x)$, using the sample $\mathcal{X}$.

In the coin tossing example, the sample contains the outcomes of the past N tosses. Then using $\mathcal{X}$, we can estimate p_o, which is the parameter that uniquely specifies the distribution. Our estimate of p_o is

$$\hat{p}_o = \frac{\#\{\text{tosses with outcome heads}\}}{\#\{\text{tosses}\}}$$

Numerically using the random variables, x^t is 1 if the outcome of toss t is heads and 0 otherwise. Given the sample {heads, heads, heads, tails,

heads, tails, tails, heads, heads}, we have $X = \{1,1,1,0,1,0,0,1,1\}$ and the estimate is

$$\hat{p}_o = \frac{\sum_{t=1}^{N} x^t}{N} = \frac{6}{9}$$

3.2 Classification

We discussed credit scoring in section 1.2.2, where we saw that in a bank, according to their past transactions, some customers are low-risk in that they paid back their loans and the bank profited from them and other customers are high-risk in that they defaulted. Analyzing this data, we would like to learn the class "high-risk customer" so that in the future, when there is a new application for a loan, we can check whether that person obeys the class description or not and thus accept or reject the application. Using our knowledge of the application, let us say that we decide that there are two pieces of information that are observable. We observe them because we have reason to believe that they give us an idea about the credibility of a customer. Let us say, for example, we observe customer's yearly income and savings, which we represent by two random variables X_1 and X_2.

It may again be claimed that if we had access to other pieces of knowledge such as the state of economy in full detail and full knowledge about the customer, his or her intention, moral codes, and so forth, whether someone is a low-risk or high-risk customer could have been deterministically calculated. But these are nonobservables and with what we can observe, the credibility of a customer is denoted by a Bernoulli random variable C conditioned on the observables $\mathbf{X} = [X_1, X_2]^T$ where $C = 1$ indicates a high-risk customer and $C = 0$ indicates a low-risk customer. Thus if we know $P(C|X_1, X_2)$, when a new application arrives with $X_1 = x_1$ and $X_2 = x_2$, we can

$$\text{choose} \begin{cases} C = 1 & \text{if } P(C = 1|x_1, x_2) > 0.5 \\ C = 0 & \text{otherwise} \end{cases}$$

or equivalently

$$\text{choose} \begin{cases} C = 1 & \text{if } P(C = 1|x_1, x_2) > P(C = 0|x_1, x_2) \\ C = 0 & \text{otherwise} \end{cases} \tag{3.1}$$

The probability of error is $1 - \max(P(C = 1|x_1, x_2), P(C = 0|x_1, x_2))$. This example is similar to the coin tossing example except that here, the

Bernoulli random variable C is conditioned on two other observable variables. Let us denote by $\mathbf{x}$ the vector of observed variables, $\mathbf{x} = [x_1, x_2]^T$.

BAYES' RULE The problem then is to be able to calculate $P(C|\mathbf{x})$. Using *Bayes' rule*, it can be written as

$$P(C|\mathbf{x}) = \frac{P(C)p(\mathbf{x}|C)}{p(\mathbf{x})} \tag{3.2}$$

PRIOR PROBABILITY $P(C = 1)$ is called the *prior probability* that C takes the value 1, which in our example corresponds to the probability that a customer is high-risk, regardless of the $\mathbf{x}$ value. It is called the prior probability because it is the knowledge we have as to the value of C *before* looking at the observables $\mathbf{x}$, satisfying

$$P(C = 0) + P(C = 1) = 1$$

CLASS LIKELIHOOD $p(\mathbf{x}|C)$ is called the *class likelihood* and is the conditional probability that an event belonging to C has the associated observation value $\mathbf{x}$. In our case, $p(x_1, x_2|C = 1)$ is the probability that a high-risk customer has his or her $X_1 = x_1$ and $X_2 = x_2$. It is what the data tells us regarding the class.

EVIDENCE $p(\mathbf{x})$, the *evidence*, is the marginal probability that an observation $\mathbf{x}$ is seen, regardless of whether it is a positive or negative example.

$$p(\mathbf{x}) = p(\mathbf{x}|C = 1)P(C = 1) + p(\mathbf{x}|C = 0)P(C = 0) \tag{3.3}$$

POSTERIOR PROBABILITY Combining the prior and what the data tells us using Bayes' rule, we calculate the *posterior probability* of the concept, $P(C|\mathbf{x})$, *after* having seen the observation, $\mathbf{x}$.

$$\text{posterior} = \frac{\text{prior} \times \text{likelihood}}{\text{evidence}}$$

Because of normalization by the evidence, the posteriors sum up to 1:

$$P(C = 0|\mathbf{x}) + P(C = 1|\mathbf{x}) = 1$$

Once we have the posteriors, we decide by using equation 3.1. For now, we assume that we know the prior and likelihoods; in later chapters, we discuss how to estimate $P(C)$ and $p(\mathbf{x}|C)$ from a given training sample.

In the general case, we have K mutually exclusive and exhaustive classes; $C_i, i = 1, \ldots, K$; for example, in optical digit recognition, the input is a bitmap image and there are ten classes. We have the prior probabilities satisfying

$$P(C_i) \geq 0 \text{ and } \sum_{i=1}^{K} P(C_i) = 1 \tag{3.4}$$

$p(\mathbf{x}|C_i)$ is the probability of seeing $\mathbf{x}$ as the input when it is known to belong to class C_i. The posterior probability of class C_i can be calculated as

$$P(C_i|\mathbf{x}) = \frac{p(\mathbf{x}|C_i)P(C_i)}{p(\mathbf{x})} = \frac{p(\mathbf{x}|C_i)P(C_i)}{\sum_{k=1}^{K} p(\mathbf{x}|C_k)P(C_k)} \tag{3.5}$$

BAYES' CLASSIFIER

and for minimum error, the *Bayes' classifier* chooses the class with the highest posterior probability; that is, we

$$\text{choose } C_i \text{ if } P(C_i|\mathbf{x}) = \max_k P(C_k|\mathbf{x}) \tag{3.6}$$

3.3 Losses and Risks

It may be the case that decisions are not equally good or costly. A financial institution when making a decision for a loan applicant should take into account the potential gain and loss as well. An accepted low-risk applicant increases profit, while a rejected high-risk applicant decreases loss. The loss for a high-risk applicant erroneously accepted may be different from the potential gain for an erroneously rejected low-risk applicant. The situation is much more critical and far from symmetry in other domains like medical diagnosis or earthquake prediction.

LOSS FUNCTION
EXPECTED RISK

Let us define action α_i as the decision to assign the input to class C_i, and λ_{ik} as the *loss* incurred for taking action α_i when the input actually belongs to C_k. Then the *expected risk* for taking action α_i is

$$R(\alpha_i|\mathbf{x}) = \sum_{k=1}^{K} \lambda_{ik} P(C_k|\mathbf{x}) \tag{3.7}$$

and we choose the action with minimum risk:

$$\text{choose } \alpha_i \text{ if } R(\alpha_i|\mathbf{x}) = \min_k R(\alpha_k|\mathbf{x}) \tag{3.8}$$

ZERO-ONE LOSS

Let us define K actions $\alpha_i, i = 1, \ldots, K$, where α_i is the action of assigning $\mathbf{x}$ to C_i. In the special case of the *zero-one loss* case where

$$\lambda_{ik} = \begin{cases} 0 & \text{if } i = k \\ 1 & \text{if } i \neq k \end{cases} \tag{3.9}$$

all correct decisions have no loss and all errors are equally costly. The risk of taking action α_i is

$$R(\alpha_i|\mathbf{x}) = \sum_{k=1}^{K} \lambda_{ik} P(C_k|\mathbf{x})$$

$$= \sum_{k \neq i} P(C_k|\mathbf{x})$$
$$= 1 - P(C_i|\mathbf{x})$$

because $\sum_k P(C_k|\mathbf{x}) = 1$. Thus to minimize risk, we choose the most probable case. In later chapters, for simplicity, we will always assume this case and choose the class with the highest posterior, but note that this is indeed a special case and rarely do applications have a symmetric, zero-one loss. In the general case, it is a simple postprocessing to go from posteriors to risks and to take the action to minimize the risk.

In some applications, wrong decisions—namely, misclassifications—may have very high cost, and it is generally required that a more complex—for example, manual—decision is made if the automatic system has low certainty of its decision. For example, if we are using an optical digit recognizer to read postal codes on envelopes, wrongly recognizing the code causes the envelope to be sent to a wrong destination.

REJECT In such a case, we define an additional action of *reject* or *doubt*, α_{K+1}, with $\alpha_i, i = 1, \ldots, K$, being the usual actions of deciding on classes $C_i, i = 1, \ldots, K$ (Duda, Hart, and Stork 2001).

A possible loss function is

$$\lambda_{ik} = \begin{cases} 0 & \text{if } i = k \\ \lambda & \text{if } i = K+1 \\ 1 & \text{otherwise} \end{cases} \tag{3.10}$$

where $0 < \lambda < 1$ is the loss incurred for choosing the $(K+1)$st action of reject. Then the risk of reject is

$$R(\alpha_{K+1}|\mathbf{x}) = \sum_{k=1}^{K} \lambda P(C_k|\mathbf{x}) = \lambda \tag{3.11}$$

and the risk of choosing class C_i is

$$R(\alpha_i|\mathbf{x}) = \sum_{k \neq i} P(C_k|\mathbf{x}) = 1 - P(C_i|\mathbf{x}) \tag{3.12}$$

The optimal decision rule is to

$$\begin{aligned} &\text{choose } C_i && \text{if } R(\alpha_i|\mathbf{x}) < R(\alpha_k|\mathbf{x}) \text{ for all } k \neq i \text{ and} \\ & && R(\alpha_i|\mathbf{x}) < R(\alpha_{K+1}|\mathbf{x}) \\ &\text{reject} && \text{if } R(\alpha_{K+1}|\mathbf{x}) < R(\alpha_i|\mathbf{x}), i = 1, \ldots, K \end{aligned} \tag{3.13}$$

Given the loss function of equation 3.10, this simplifies to

$$\begin{array}{ll} \text{choose } C_i & \text{if } P(C_i|\boldsymbol{x}) > P(C_k|\boldsymbol{x}) \text{ for all } k \neq i \text{ and} \\ & P(C_i|\boldsymbol{x}) > 1 - \lambda \\ \text{reject} & \text{otherwise} \end{array} \tag{3.14}$$

This whole approach is meaningful if $0 < \lambda < 1$: If $\lambda = 0$, we always reject; a reject is as good as a correct classification. If $\lambda \geq 1$, we never reject; a reject is as costly as, or costlier than, an error.

3.4 Discriminant Functions

DISCRIMINANT FUNCTIONS

Classification can also be seen as implementing a set of *discriminant functions*, $g_i(\boldsymbol{x}), i = 1, \ldots, K$, such that we

$$\text{choose } C_i \text{ if } g_i(\boldsymbol{x}) = \max_k g_k(\boldsymbol{x}) \tag{3.15}$$

We can represent the Bayes' classifier in this way by setting

$$g_i(\boldsymbol{x}) = -R(\alpha_i|\boldsymbol{x})$$

and the maximum discriminant function corresponds to minimum conditional risk. When we use the zero-one loss function, we have

$$g_i(\boldsymbol{x}) = P(C_i|\boldsymbol{x})$$

or ignoring the common normalizing term, $p(\boldsymbol{x})$, we can write

$$g_i(\boldsymbol{x}) = p(\boldsymbol{x}|C_i)P(C_i)$$

DECISION REGIONS

This divides the feature space into K *decision regions* $\mathcal{R}_1, \ldots, \mathcal{R}_K$, where $\mathcal{R}_i = \{\boldsymbol{x}|g_i(\boldsymbol{x}) = \max_k g_k(\boldsymbol{x})\}$. The regions are separated by *decision boundaries*, surfaces in feature space where ties occur among the largest discriminant functions (see figure 3.1).

When there are two classes, we can define a single discriminant

$$g(\boldsymbol{x}) = g_1(\boldsymbol{x}) - g_2(\boldsymbol{x})$$

and we

$$\text{choose} \begin{cases} C_1 & \text{if } g(\boldsymbol{x}) > 0 \\ C_2 & \text{otherwise} \end{cases}$$

DICHOTOMIZER
POLYCHOTOMIZER

An example is a two-class learning problem where the positive examples can be taken as C_1 and the negative examples as C_2. When $K = 2$, the classification system is a *dichotomizer* and for $K \geq 3$, it is a *polychotomizer.*

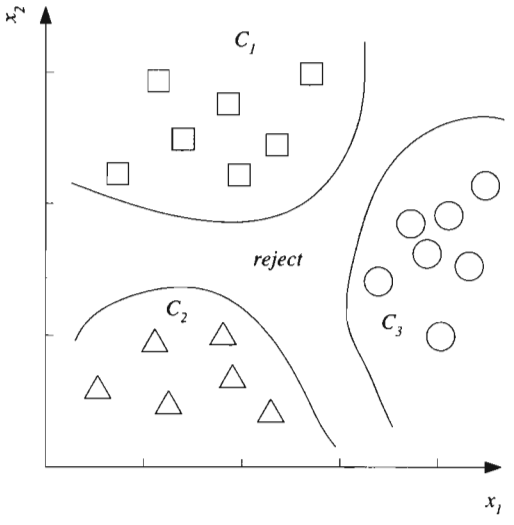

Figure 3.1 Example of decision regions and decision boundaries.

3.5 Utility Theory

UTILITY THEORY

In equation 3.7, we defined the expected risk and chose the action that minimizes expected risk. We now generalize this to *utility theory*, which is concerned with making rational decisions when we are uncertain about the state. Let us say that given evidence $\mathbf{x}$, the probability of state S_k is calculated as $P(S_k|\mathbf{x})$. We define a *utility function*, U_{ik}, which measures how good it is to take action α_i when the state is S_k. The *expected utility* is

UTILITY FUNCTION

EXPECTED UTILITY

$$EU(\alpha_i|\mathbf{x}) = \sum_k U_{ik} P(S_k|\mathbf{x}) \tag{3.16}$$

A rational decision maker chooses the action that maximizes the expected utility

$$\text{Choose } \alpha_i \text{ if } EU(\alpha_i|\mathbf{x}) = \max_j EU(\alpha_j|\mathbf{x}) \tag{3.17}$$

In the context of classification, decisions correspond to choosing one of the classes, and maximizing the expected utility is equivalent to minimizing expected risk. U_{ik} are generally measured in monetary terms, and this gives us a way to define the loss matrix λ_{ik} as well. For example, in

defining a reject option (equation 3.10), if we know how much money we will gain as a result of a correct decision, how much money we will lose on a wrong decision, and how costly it is to defer the decision to a human expert, depending on the particular application we have, we can fill in the correct values U_{ik} in a currency unit, instead of 0, λ, and 1, and make our decision so as to maximize expected earnings.

In the case of reject, we are choosing between the automatic decision made by the computer program and human decision that is costlier but assumed to have a higher probability of being correct. Similarly one can imagine a cascade of multiple automatic decision makers, which as we proceed are costlier but have a higher chance of being correct.

Note that maximizing expected utility is just one possibility; one may define other types of rational behavior, for example, minimizing worst possible loss.

3.6 Value of Information

In medical diagnosis, there are many tests that can be applied to a patient. Taking the pulse has no cost but doing a blood test is costly—there is both the cost of the test and the inconvenience to the patient—but the blood test may give us much more information. Generally we assume that all observable features are observed but this may not always be the case; certain features may be costly to observe as in the case of a blood test in medical diagnosis, and we would like to observe them only when they are really needed. So we would like to be able to assess the value of information that additional features may provide.

Let us say we have $\boldsymbol{x}$ of already observed features. Then the expected utility of current best action is

$$EU(\boldsymbol{x}) = \max_i \sum_k U_{ik} P(S_k|\boldsymbol{x})$$

If we observe the new feature z and use it with $\boldsymbol{x}$, then the expected utility of best action is

$$EU(\boldsymbol{x}, z) = \max_i \sum_k U_{ik} P(S_k|\boldsymbol{x}, z)$$

VALUE OF INFORMATION

If $EU(\boldsymbol{x}, z) > EU(\boldsymbol{x})$, then we can say that z is useful, and this difference is the *value of information* provided by z. But we should also take into account the cost of observing z, as well as processing it: $P(S_k|\boldsymbol{x}, z)$

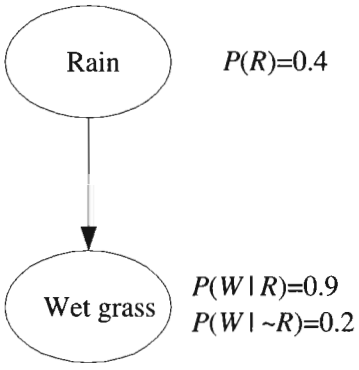

Figure 3.2 Bayesian network modeling that rain is the cause of wet grass.

uses both $\mathbf{x}$ and z, and is more complex than $P(S_k|\mathbf{x})$. z may be added as a new feature only if its contribution is worth more than its additional complexity.

3.7 Bayesian Networks

BELIEF NETWORKS
PROBABILISTIC NETWORKS
GRAPHICAL MODELS

Bayesian networks, also called *belief networks* or *probabilistic networks*, are *graphical models* for representing the interaction between variables visually. A Bayesian network is composed of nodes and arcs between the nodes. Each node corresponds to a random variable, X, and has a value corresponding to the probability of the random variable, $P(X)$. If there is a directed arc from node X to node Y, this indicates that X has a *direct influence* on Y. This influence is specified by the conditional probability $P(Y|X)$. The network is a *directed acyclic graph* (DAG), namely, there are no cycles. The nodes and the arcs between the nodes define the *structure* of the network, and the conditional probabilities are the *parameters* given the structure.

DIRECTED ACYCLIC GRAPH

A simple example is given in figure 3.2, which models that rain causes the grass to get wet. It rains on 40 percent of the days and when it rains, there is a 90 percent chance that the grass gets wet; maybe 10 percent of the time it does not rain long enough for us to really consider the grass wet enough. The random variables in this example are binary: true or false. There is a 20 percent probability that the grass gets wet without its actually raining, for example, when a sprinkler is used.

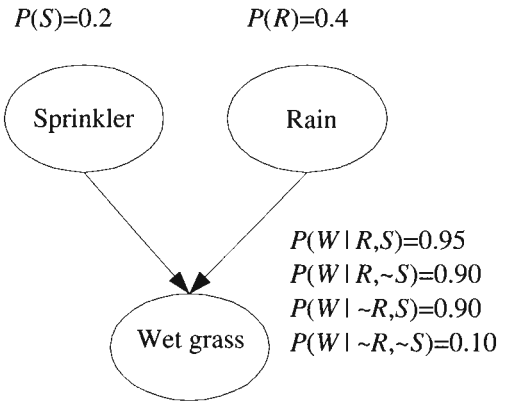

Figure 3.3 Rain and sprinkler are the two causes of wet grass.

We see that these three values completely specify the joint distribution of $P(R, W)$. If $P(R) = 0.4$, then $P(\sim R) = 0.6$ and similarly $P(\sim W|R) = 0.1$ and $P(\sim W|\sim R) = 0.8$.

CAUSAL GRAPH

This is a *causal graph* in that it explains that the major cause of wet grass is rain. Bayes' rule allows us to invert the dependencies and have a *diagnosis.* For example, knowing that the grass is wet, the probability that it rained can be calculated:

$$\begin{aligned} P(R|W) &= \frac{P(W|R)P(R)}{P(W)} \\ &= \frac{P(W|R)P(R)}{P(W|R)P(R) + P(W|\sim R)P(\sim R)} \\ &= \frac{0.9 \times 0.4}{0.9 \times 0.4 + 0.2 \times 0.6} = 0.75 \end{aligned}$$

The denominator $P(W)$ is the probability of having wet grass, regardless of whether it rained or not. Note that knowing that the grass is wet increased the probability of rain from 0.4 to 0.75; this is because $P(W|R)$ is high and $P(W|\sim R)$ is low.

Let us now say that we want to include sprinkler as another cause of wet grass. This is shown in figure 3.3. Node W has two *parents,* R and S, and thus its probability is conditioned on the values of those two, $P(W|R, S)$. We can calculate the probability of having wet grass given the sprinkler is on, not knowing whether it rained or not. This is a causal

(predictive) inference:

$$\begin{aligned} P(W|S) &= P(W|R,S)P(R|S) + P(W|\sim R,S)P(\sim R|S) \\ &= P(W|R,S)P(R) + P(W|\sim R,S)P(\sim R) \\ &= 0.95 \times 0.4 + 0.9 \times 0.6 = 0.92 \end{aligned}$$

$P(R|S) = P(R)$ because according to figure 3.3, R and S are independent. We can calculate the probability that the sprinkler is on, given that the grass is wet. This is a diagnostic inference.

$$P(S|W) = \frac{P(W|S)P(S)}{P(W)} = \frac{0.92 \times 0.2}{0.52} = 0.35$$

where

$$\begin{aligned} P(W) &= P(W|R,S)P(R,S) + P(W|\sim R,S)P(\sim R,S) \\ &\quad + P(W|R,\sim S)P(R,\sim S) + P(W|\sim R,\sim S)P(\sim R,\sim S) \\ &= P(W|R,S)P(R)P(S) + P(W|\sim R,S)P(\sim R)P(S) \\ &\quad + P(W|R,\sim S)P(R)P(\sim S) + P(W|\sim R,\sim S)P(\sim R)P(\sim S) \\ &= 0.95 \times 0.4 \times 0.2 + 0.9 \times 0.6 \times 0.2 + 0.9 \times 0.4 \times 0.8 \\ &\quad + 0.1 \times 0.6 \times 0.8 \\ &= 0.52 \end{aligned}$$

Knowing that the grass is wet increased the probability of having the sprinkler on. Now let us assume that it rained. Then we have

$$\begin{aligned} P(S|R,W) &= \frac{P(W|R,S)P(S|R)}{P(W|R)} = \frac{P(W|R,S)P(S)}{P(W|R)} \\ &= 0.21 \end{aligned}$$

EXPLAINING AWAY

Note that this value is less than $P(S|W)$. This is called *explaining away;* given that we know it rained, the probability of sprinkler causing the wet grass decreases. Knowing that the grass is wet, rain and sprinkler become dependent.

Figure 3.3 shows that R and S are independent. However we may think that they are actually dependent in the presence of another variable: we usually do not turn on the sprinkler if it is likely to rain. So a better graph is given in figure 3.4. If it is cloudy, it is likely to rain and we are likely to find the sprinkler off. We can, for example, calculate the probability of having wet grass if it is cloudy:

$$P(W|C) = P(W|R,S,C)P(R,S|C)$$

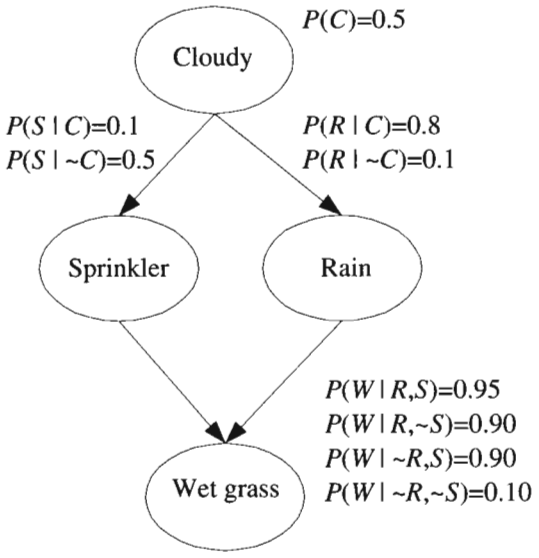

Figure 3.4 If it is cloudy, it is likely that it will rain and we will not use the sprinkler.

$$
\begin{aligned}
& + P(W|{\sim}R,S,C)P({\sim}R,S|C) \\
& + P(W|R,{\sim}S,C)P(R,{\sim}S|C) \\
& + P(W|{\sim}R,{\sim}S,C)P({\sim}R,{\sim}S|C) \\
= \; & P(W|R,S)P(R|C)P(S|C) \\
& + P(W|{\sim}R,S)P({\sim}R|C)P(S|C) \\
& + P(W|R,{\sim}S)P(R|C)P({\sim}S|C) \\
& + P(W|{\sim}R,{\sim}S)P({\sim}R|C)P({\sim}S|C)
\end{aligned}
$$

where we have used that $P(W|R,S,C) = P(W|R,S)$; given R and S, W is independent of C. Similarly $P(R,S|C) = P(R|C)P(S|C)$; given C, R and S are independent. This is the advantage of Bayesian networks, which explicitly encode independencies and allow breaking down inference into calculation over small groups of variables.

We can make the network even more detailed depending on what we can observe. For example, we may have a cat that likes taking a walk on the roof and makes noise (even if the roof is not a hot tin one). The cat does not go out when it rains (figure 3.5). Then, for example, we can

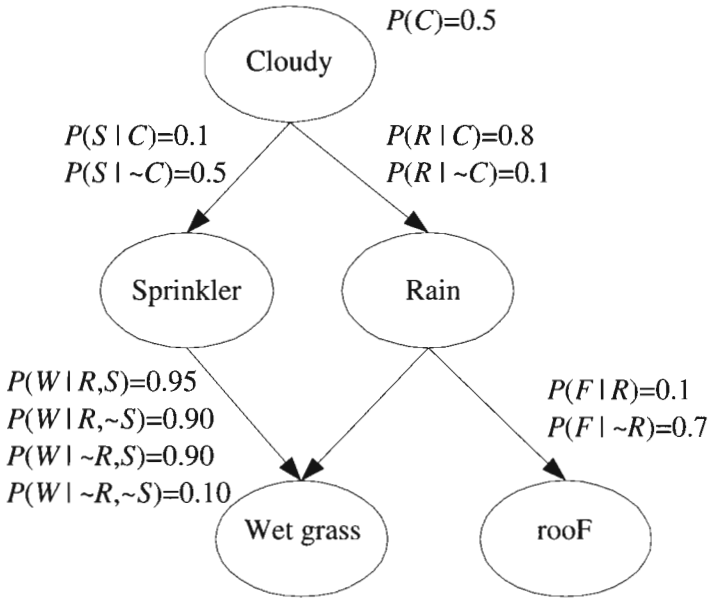

Figure 3.5 Rain not only makes the grass wet but also disturbs the cat who normally makes noise on the roof.

calculate the probability that we hear the cat on the roof given that it is cloudy, namely, $P(F|C)$, or even $P(F|S)$.

The graphical representation is visual and helps understanding. The network represents conditional independence statements and allows us to break down the problem of representing the joint distribution of many variables into *local* structures; this eases both analysis and computation. Figure 3.5 represents a joint density of five binary variables that would normally require thirty-one values ($2^5 - 1$) to be stored, whereas here there are only eleven. If each node has a small number of parents, the complexity decreases from exponential to linear (in the number of nodes). As we have seen earlier, inference is also easier as the joint density is broken down into conditional densities of smaller groups of variables:

$$P(C,S,R,W,F) = P(C)P(S|C)P(R|C)P(W|S,R)P(F|R) \tag{3.18}$$

Though in this example we use binary variables, it is clear that the variables can be discrete with any number of possible values, or they can

be continuous. This only changes the conditional probabilities. In the general case, when we have variables $X_1, \ldots, X_d$,

$$P(X_1, \ldots, X_d) = \prod_{i=1}^{d} P(X_i | \text{parents}(X_i)) \tag{3.19}$$

Then given any subset of X_i, namely, setting them to certain values due to evidence, we can calculate the probability distribution of some other subset of X_i by marginalizing over the joint. This is costly because it requires calculating an exponential number of joint probability combinations, even though each of them can be simplified as in equation 3.18.

BELIEF PROPAGATION

There exists an efficient algorithm called *belief propagation* (Pearl 1988) that we can use for inference when the network is a tree. There exists also an algorithm that converts a given directed acyclic graph to a tree, named

JUNCTION TREE

the *junction tree,* by clustering variables, so that belief propagation can be done (Lauritzen and Spiegelhalter 1988).

One major advantage of using a Bayesian network is that we do not need to designate explicitly certain variables as input and certain others as output. The value of any set of variables can be established through evidence and the probabilities of any other set of variables can be inferred, and the difference between unsupervised and supervised learning becomes blurry.

CAUSALITY

It should be stressed at this point that a link from a node X does not, and need not, always imply a *causality.* It only implies a *direct influence* of X over Y in the sense that the probability of Y is conditioned on the value of X, and two nodes may have a link between them even if there is no direct cause. It is preferable to have the causal relations in constructing the network by providing an explanation of how the data is generated (Pearl 2000) but such causes may not always be accessible.

Most of the methods that we discuss in this book can be written down as a Bayesian network. For example, for the case of classification that we discussed in section 3.2, the corresponding Bayesian network is shown in figure 3.6. Bayes' rule as given in equation 3.2 allows calculating $p(C|\mathbf{x})$, namely, a diagnosis.

NAIVE BAYES' CLASSIFIER

If the inputs are independent, the network is written as in figure 3.7, which is called the *naive Bayes' classifier,* because it ignores possible dependencies, namely, correlations, among the inputs and reduces a multi-

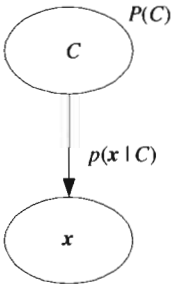

Figure 3.6 Bayesian network for classification.

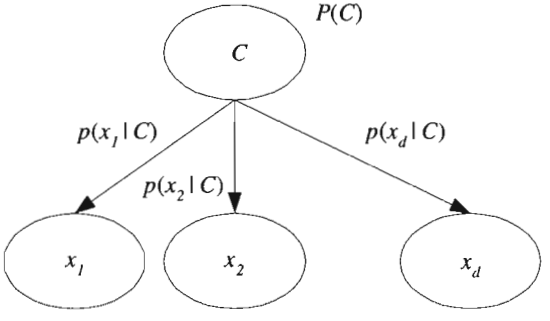

Figure 3.7 Naive Bayes' classifier is a Bayesian network for classification assuming independent inputs.

variate problem to a group of univariate problems:

$$p(\mathbf{x}|C_i) = \prod_{j=1}^{d} p(x_j|C_i)$$

HIDDEN VARIABLES

In a problem, there may also be *hidden variables* whose values are never known through evidence. The advantage of using hidden variables is that the dependency structure can be more easily defined. For example, in basket analysis when we want to find the dependencies among items sold, let us say we know that there is a dependency among "baby food," "diapers," and "milk" in that a customer buying one of these is very much likely to buy the other two. Instead of putting (noncausal) arcs among these three, we may designate a hidden node "baby at home" as the hidden cause of the consumption of these three items. When there

are hidden nodes, their values are estimated given the values of observed nodes and filled in.

The learning algorithms used for learning the parameters of a Bayesian network are not different from the methods we discuss in later chapters (Buntine 1996). They are basically for estimating the conditional probabilities. Learning the structure is much more difficult. Although there are also algorithms proposed for this aim, basically it is the human expert who defines causal relationships among variables and creates hierarchies of small groups of variables.

3.8 Influence Diagrams

INFLUENCE DIAGRAMS

Just as we have previously generalized from probabilities to actions with risks, *influence diagrams* are graphical models that allow the generalization of Bayesian networks to include decisions and utilities. An influence diagram contains *chance nodes* representing random variables that we use in Bayesian networks. It also has decision nodes and a utility node. A *decision node* represents a choice of actions. A *utility node* is where the utility is calculated. Decisions may be based on chance nodes and may affect other chance nodes and the utility node.

Inference on an influence diagram is an extension to inference on a Bayesian network. Given evidence on some of the chance nodes, this evidence is propagated and for each possible decision, the utility is calculated and the decision having the highest utility is chosen. The influence diagram for classification of a given input is shown in figure 3.8. Given the input, the decision node decides on a class and for each choice, we incur a certain utility (risk).

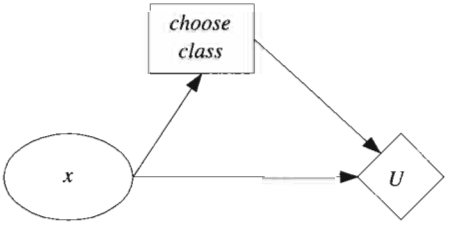

Figure 3.8 Influence diagram corresponding to classification. Depending on input x, a class is chosen that incurs a certain utility (risk).

3.9 Association Rules

ASSOCIATION RULE
BASKET ANALYSIS

An *association rule* is an implication of the form $X \rightarrow Y$. One example of association rules is in *basket analysis* where we want to find the dependency between two items X and Y. The typical application is in retail where X and Y are items sold (section 1.2.1).

In learning association rules, there are two measures that are calculated:

CONFIDENCE

- *Confidence* of the association rule $X \rightarrow Y$:

$$\begin{aligned} \text{Confidence}(X \rightarrow Y) \equiv P(Y|X) &= \frac{P(X,Y)}{P(X)} \\ &= \frac{\#\{\text{customers who bought } X \text{ and } Y\}}{\#\{\text{customers who bought } X\}} \end{aligned} \tag{3.20}$$

SUPPORT

- *Support* of the association rule $X \rightarrow Y$:

$$\text{Support}(X,Y) \equiv P(X,Y) = \frac{\#\{\text{customers who bought } X \text{ and } Y\}}{\#\{\text{customers}\}} \tag{3.21}$$

Confidence is the conditional probability, $P(Y|X)$, which is what we normally calculate. To be able to say that the rule holds with enough confidence, this value should be close to 1 and significantly larger than $P(Y)$, the overall probability of people buying Y. We are also interested in maximizing the *support* of the rule, because even if there is a dependency with a strong confidence value, if the number of such customers is small, the rule is worthless. Support shows the statistical significance of the rule whereas confidence shows the strength of the rule.

The minimum support and confidence values are set by the company, and all rules with higher support and confidence are searched for in the database. These formulas for support and confidence can easily be generalized to more than two items, such that X and Y are disjoint sets of items. For example, $P(Y|X,Z)$ is a three-item set that is more important than a two-item set. Because a sales database is generally very large, we want to find the dependencies by doing a small number of passes over the database. There is an efficient algorithm, called *Apriori* (Agrawal et al. 1996), that does this.

APRIORI ALGORITHM

3.10 Notes

Making decisions under uncertainty has a long history, and over time humanity has looked at all sorts of strange places for evidence to remove the uncertainty: stars, crystal balls, and coffee cups. Reasoning from meaningful evidence using probability theory is only a few hundred years old; see Newman 1988 for the history of probability and statistics and some very early articles by Laplace, Bernoulli, and others who have founded the theory.

Russell and Norvig (1995) give an excellent discussion of utility theory and the value of information, also discussing the assignment of utilities in monetary terms. Shafer and Pearl 1986 is an early collection of articles on reasoning under uncertainty. Pearl's 1988 book is a classic, and his recent book (Pearl 2000) investigates the concept of causality in more detail. Jensen's 1996 book is a very readable introduction to Bayesian networks. A more formal treatment is given in Lauritzen 1996. The paper by Huang and Darwiche (1994) is a good tutorial explaining the construction of the junction tree and inference over the tree in detail. When the network is large, exact inference becomes infeasible; one can use stochastic sampling (Andrieu et al. 2003) or variational methods (Jordan et al. 1999). Buntine 1996 contains a literature survey on learning in Bayesian networks and Jordan 1999 is a collection of more recent work. The construction of the network structure by an expert as well as methods for learning the structure from data are discussed in Cowell et al. 1999.

The Association for Uncertainty in Artificial Intelligence has a Web page at http://www.auai.org where there is a good selection of tutorial papers and links to public domain programs. Recent work on Bayesian networks can be found in the proceedings of the *Uncertainty in Artificial Intelligence* (UAI).

3.11 Exercises

LIKELIHOOD RATIO

1. In a two-class problem, the *likelihood ratio* is

$$\frac{p(\mathbf{x}|C_1)}{p(\mathbf{x}|C_2)}$$

Write the discriminant function in terms of the likelihood ratio.

LOG ODDS

2. In a two-class problem, the *log odds* is defined as

$$\log \frac{P(C_1|\mathbf{x})}{P(C_2|\mathbf{x})}$$

Write the discriminant function in terms of the log odds.

3. In a two-class, two-action problem, if the loss function is $\lambda_{11} = \lambda_{22} = 0$, $\lambda_{12} = 10$, and $\lambda_{21} = 1$, write the optimal decision rule.
4. Somebody tosses a fair coin and if the result is heads, you get nothing, otherwise you get \$5. How much would you pay to play this game? What if the win is \$500 instead of \$5?
5. In figure 3.4, calculate $P(C|W)$.
6. In figure 3.5, calculate $P(F|C)$.
7. Given the structure in figure 3.5 and a sample $\mathcal{X}$ containing observations as

Cloudy	Sprinkler	Rain	Wet grass	Roof
No	Yes	No	Yes	Yes
Yes	No	Yes	No	No
⋮	⋮	⋮	⋮	⋮

how do you learn the probabilities?

8. Generalize the confidence and support formulas for basket analysis to calculate k-dependencies, namely, $P(Y|X_1, \ldots, X_k)$.
9. If, in basket analysis, associated with each item sold, we also have a number indicating how much the customer enjoyed the product, for example, in a scale of 0 to 10, how can you use this extra information to calculate which item to propose to a customer?

4 *Parametric Methods*

Having discussed how to make optimal decisions when the uncertainty is modeled using probabilities, we now see how we can estimate these probabilities from a given training set. We start with the parametric approach for classification and regression. We discuss the semiparametric and nonparametric approaches in later chapters. We introduce model selection methods for trading off the model complexity and the empirical error.

4.1 Introduction

A STATISTIC is any value that is calculated from a given sample. In statistical inference, we make a decision using the information provided by a sample. Our first approach is parametric where we assume that the sample is drawn from some distribution that obeys a known model, for example, Gaussian. The advantage of the parametric approach is that the model is defined up to a small number of parameters—for example, mean, variance—the *sufficient statistics* of the distribution. Once those parameters are estimated from the sample, the whole distribution is known. We estimate the parameters of the distribution from the given sample, plug in these estimates to the assumed model, and get an estimated distribution, which we then use to make a decision. The method we use to estimate the parameters of a distribution is maximum likelihood estimation. We also discuss Bayesian estimation, which has recently become popular with the availability of large computing power.

We start with *density estimation,* which is the general case of estimating $p(x)$. We use this for *classification* where the estimated densities are the class densities $p(x|C_i)$ and $P(C_i)$, to be able to calculate the posterior

$P(C_i|x)$ and make our decision. We then discuss *regression* where the estimated density is $p(y|x)$. In this chapter, x is one-dimensional and thus the densities are univariate. We generalize to the multivariate case in chapter 5.

4.2 Maximum Likelihood Estimation

Let us say we have an independent and identically distributed (iid) sample $\mathcal{X} = \{x^t\}_{t=1}^N$. We assume that x^t are instances drawn from some known probability density family, $p(x|\theta)$, defined up to parameters, θ:

$$x^t \sim p(x|\theta)$$

LIKELIHOOD

We want to find θ that makes sampling x^t from $p(x|\theta)$ as likely as possible. Because x^t are independent, the *likelihood* of sample $\mathcal{X}$ given the parameter θ is the product of the likelihoods of the individual points:

$$l(\theta) \equiv p(\mathcal{X}|\theta) = \prod_{t=1}^{N} p(x^t|\theta) \tag{4.1}$$

MAXIMUM LIKELIHOOD ESTIMATION

In *maximum likelihood estimation,* we are interested in finding θ that makes $\mathcal{X}$ the most likely to be drawn. We thus search for θ that maximizes the likelihood of the sample, which we denote by $l(\theta|\mathcal{X})$. We can maximize the log of the likelihood without changing the value where it takes its maximum. $\log(\cdot)$ converts the product into a sum and leads to further computational simplification when certain densities are assumed, for example, containing exponents. The *log likelihood* is defined as

LOG LIKELIHOOD

$$\mathcal{L}(\theta|\mathcal{X}) \equiv \log l(\theta|\mathcal{X}) = \sum_{t=1}^{N} \log p(x^t|\theta) \tag{4.2}$$

Let us now see some distributions that arise in the applications we are interested in. If we have a two-class problem, the distribution we use is *Bernoulli.* When there are $K > 2$ classes, its generalization is the *multinomial. Gaussian* (*normal*) density is the one most frequently used for modeling class-conditional input densities. For these three distributions, we discuss the maximum likelihood estimators (MLE) of their parameters.

4.2.1 Bernoulli Density

In a Bernoulli distribution there are two outcomes: An event occurs or it does not, for example, an instance is a positive example of the class,

or it is not. The event occurs and the Bernoulli random variable X takes the value 1 with probability p, and the nonoccurrence of the event has probability $1 - p$ and this is denoted by X taking the value 0. This is written as

$$P(x) = p^x(1-p)^{1-x}, x \in \{0,1\} \tag{4.3}$$

p is the only parameter and given an iid sample $\mathcal{X} = \{x^t\}_{t=1}^N$, where $x^t \in \{0,1\}$, we want to calculate its estimator, $\hat{p}$. The log likelihood is

$$\begin{aligned}\mathcal{L}(p|\mathcal{X}) &= \log \prod_{t=1}^{N} p^{(x^t)}(1-p)^{(1-x^t)} \\ &= \sum_t x^t \log p + \left(N - \sum_t x^t\right) \log(1-p)\end{aligned}$$

$\hat{p}$ that maximizes the log likelihood can be found by solving for $d\mathcal{L}/dp = 0$.

$$\hat{p} = \frac{\sum_t x^t}{N} \tag{4.4}$$

The estimate for p is the ratio of the number of occurrences of the event to the number of experiments. Remembering that if X is Bernoulli with p, $E[X] = p$, and as expected, the maximum likelihood estimator of the mean is the sample average.

4.2.2 Multinomial Density

Consider the generalization of Bernoulli where instead of two states, the outcome of a random event is one of K mutually exclusive and exhaustive states, for example, classes, each of which has a probability of occurring p_i with $\sum_{i=1}^K p_i = 1$. Let $x_1, x_2, \ldots, x_K$ are the indicator variables where x_i is 1 if the outcome is state i and 0 otherwise.

$$p(x_1, x_2, \ldots, x_K) = \prod_{i=1}^{K} p_i^{x_i} \tag{4.5}$$

Let us say we do N such independent experiments with outcomes $\mathcal{X} = \{\mathbf{x}^t\}_{t=1}^N$ where

$$x_i^t = \begin{cases} 1 & \text{if experiment } t \text{ chooses state } i \\ 0 & \text{otherwise} \end{cases}$$

with $\sum_i x_i^t = 1$. The MLE of p_i is

$$\hat{p}_i = \frac{\sum_t x_i^t}{N} \tag{4.6}$$

The estimate for the probability of state i is the ratio of experiments with outcome of state i to the total number of experiments. There are two ways one can get this: If x_i are 0/1, then they can be thought of as K separate Bernoulli experiments. Or, one can explicitly write the log likelihood and find p_i that maximize it (subject to the condition that $\sum_i p_i = 1$).

4.2.3 Gaussian (Normal) Density

X is Gaussian (normal) distributed with mean μ and variance σ^2, denoted as $\mathcal{N}(\mu, \sigma^2)$, if its density function is

$$p(x) = \frac{1}{\sqrt{2\pi}\sigma} \exp\left[-\frac{(x-\mu)^2}{2\sigma^2}\right], -\infty < x < \infty \tag{4.7}$$

Given a sample $\mathcal{X} = \{x^t\}_{t=1}^N$ with $x^t \sim \mathcal{N}(\mu, \sigma^2)$, the log likelihood of a Gaussian sample is

$$\mathcal{L}(\mu, \sigma | \mathcal{X}) = -\frac{N}{2}\log(2\pi) - N\log\sigma - \frac{\sum_t (x^t - \mu)^2}{2\sigma^2}$$

The MLE are

$$\begin{aligned} m &= \frac{\sum_t x^t}{N} \\ s^2 &= \frac{\sum_t (x^t - m)^2}{N} \end{aligned} \tag{4.8}$$

We follow the usual convention and use Greek letters for the population parameters and Roman letters for their estimates from the sample. Sometimes, the hat (circumflex) is also used to denote the estimator, for example, $\hat{\mu}$.

4.3 Evaluating an Estimator: Bias and Variance

Let $\mathcal{X}$ be a sample from a population specified up to a parameter θ, and let $d = d(\mathcal{X})$ be an estimator of θ. To evaluate the quality of this estimator, we can measure how much it is different from θ, that is, $(d(\mathcal{X}) - \theta)^2$. But since it is a random variable (it depends on the sample), we need to

MEAN SQUARE ERROR

average this over possible $\mathcal{X}$ and consider $r(d, \theta)$, the *mean square error* of the estimator d defined as

$$r(d, \theta) = E[(d(\mathcal{X}) - \theta)^2] \tag{4.9}$$

BIAS

The *bias* of an estimator is given as

$$b_\theta(d) = E[d(\mathcal{X})] - \theta \tag{4.10}$$

UNBIASED ESTIMATOR

If $b_\theta(d) = 0$ for all θ values, then we say that d is an *unbiased estimator* of θ. For example, with x^t drawn from some density with mean μ, the sample average, m, is an unbiased estimator of the mean, μ, because

$$E[m] = E\left[\frac{\sum_t x^t}{N}\right] = \frac{1}{N}\sum_t E[x^t] = \frac{N\mu}{N} = \mu$$

This means that though on a particular sample, m may be different from μ, if we take many such samples, $\mathcal{X}_i$, and estimate many $m_i = m(\mathcal{X}_i)$, *their* average will get close to μ as the number of such samples increases. m is also a *consistent* estimator, that is, $\text{Var}(m) \to 0$ as $N \to \infty$.

$$\text{Var}(m) = \text{Var}\left(\frac{\sum_t x^t}{N}\right) = \frac{1}{N^2}\sum_t \text{Var}(x^t) = \frac{N\sigma^2}{N^2} = \frac{\sigma^2}{N}$$

As N, the number of points in the sample, gets larger, m deviates less from μ. Let us now check, s^2, the MLE of σ^2:

$$\begin{aligned} s^2 &= \frac{\sum_t (x^t - m)^2}{N} = \frac{\sum_t (x^t)^2 - Nm^2}{N} \\ E[s^2] &= \frac{\sum_t E[(x^t)^2] - N \cdot E[m^2]}{N} \end{aligned}$$

Given that $\text{Var}(X) = E[X^2] - E[X]^2$, we get $E[X^2] = \text{Var}(X) + E[X]^2$ and

$$E[(x^t)^2] = \sigma^2 + \mu^2, E[m^2] = \sigma^2/N + \mu^2$$

Then we have

$$E[s^2] = \frac{N(\sigma^2 + \mu^2) - N(\sigma^2/N + \mu^2)}{N} = \left(\frac{N-1}{N}\right)\sigma^2 \neq \sigma^2$$

which shows that s^2 is a biased estimator of σ^2. $(N/(N-1))s^2$ is an unbiased estimator. However when N is large, the difference is negligable. This is an example of an *asymptotically unbiased estimator* whose bias goes to 0 as N goes to infinity.

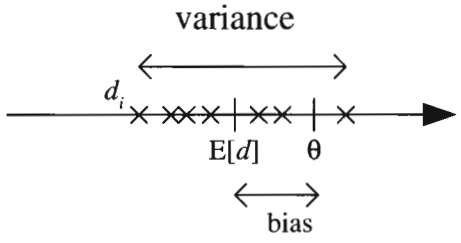

Figure 4.1 θ is the parameter to be estimated. d_i are several estimates (denoted by '$\times$') over different samples. Bias is the difference between the expected value of d and θ. Variance is how much d_i are scattered around the expected value. We would like both to be small.

The mean square error can be rewritten as follows (d is short for $d(X)$):

$$\begin{aligned} r(d,\theta) &= E\left[(d-\theta)^2\right] \\ &= E\left[(d-E[d]+E[d]-\theta)^2\right] \\ &= E\left[(d-E[d])^2+(E[d]-\theta)^2+2(E[d]-\theta)(d-E[d])\right] \\ &= E\left[(d-E[d])^2\right]+E\left[(E[d]-\theta)^2\right]+2E\left[(E[d]-\theta)(d-E[d])\right] \\ &= E\left[(d-E[d])^2\right]+(E[d]-\theta)^2+2(E[d]-\theta)E[d-E[d]] \\ &= \underbrace{E\left[(d-E[d])^2\right]}_{variance}+\underbrace{(E[d]-\theta)^2}_{bias^2} \end{aligned} \tag{4.11}$$

The two equalities follow because $E[d]$ is a constant and therefore $E[d]-\theta$ also is a constant, and because $E[d-E[d]] = E[d]-E[d] = 0$. In equation 4.11, the first term is the *variance* that measures how much, on average, d_i vary around the expected value (going from one dataset to another), and the second term is the *bias* that measures how much the expected value varies from the correct value θ (figure 4.1). We then write error as the sum of these two terms, the variance and the square of the bias:

VARIANCE

$$r(d,\theta) = \text{Var}(d) + (b_\theta(d))^2 \tag{4.12}$$

4.4 The Bayes' Estimator

Sometimes, before looking at a sample, we (or experts of the application) may have some *prior* information on the possible value range that a parameter, θ, may take. This information is quite useful and should be used, especially when the sample is small. The prior information does not tell us exactly what the parameter value is (otherwise we would not need the sample), and we model this uncertainty by viewing θ as a random variable and by defining a prior density for it, $p(\theta)$. For example, let us say we are told that θ is approximately normal and with 90 percent confidence, θ lies between 5 and 9, symmetrically around 7. Then we can write $p(\theta)$ to be normal with mean 7 and because

$$\begin{aligned} P\{-1.64 < \frac{\theta - \mu}{\sigma} < 1.64\} &= 0.9 \\ P\{\mu - 1.64\sigma < \theta < \mu + 1.64\sigma\} &= 0.9 \end{aligned}$$

we take $1.64\sigma = 2$ and use $\sigma = 2/1.64$. We can thus assume $p(\theta) \sim \mathcal{N}(7, (2/1.64)^2)$.

PRIOR DENSITY

The *prior density*, $p(\theta)$, tells us the likely values that θ may take *before* looking at the sample. We combine this with what the sample data tells us, namely, the likelihood density, $p(\mathcal{X}|\theta)$, using Bayes' rule, and get the

POSTERIOR DENSITY

posterior density of θ, which tells us the likely θ values *after* looking at the sample:

$$p(\theta|\mathcal{X}) = \frac{p(\mathcal{X}|\theta)p(\theta)}{p(\mathcal{X})} = \frac{p(\mathcal{X}|\theta)p(\theta)}{\int p(\mathcal{X}|\theta')p(\theta')d\theta'} \tag{4.13}$$

For estimating the density at x, we have

$$\begin{aligned} p(x|\mathcal{X}) &= \int p(x, \theta|\mathcal{X})d\theta \\ &= \int p(x|\theta, \mathcal{X})p(\theta|\mathcal{X})d\theta \\ &= \int p(x|\theta)p(\theta|\mathcal{X})d\theta \end{aligned}$$

$p(x|\theta, \mathcal{X}) = p(x|\theta)$ because once we know θ, the sufficient statistics, we know everything about the distribution. Thus we are taking an average over predictions using all values of θ, weighted by their probabilities. If we are doing a prediction in the form, $y = g(x|\theta)$, as in regression, then we have

$$y = \int g(x|\theta)p(\theta|\mathcal{X})d\theta$$

Evaluating the integrals may be quite difficult, except in cases where the posterior has a nice form. When the full integration is not feasible, we reduce it to a single point. If we can assume that $p(\theta|\mathcal{X})$ has a narrow peak around its mode, then using the *maximum a posteriori* (MAP) *estimate* will make the calculation easier:

MAXIMUM A POSTERIORI ESTIMATE

$$\theta_{MAP} = \arg\max_{\theta} p(\theta|\mathcal{X}) \tag{4.14}$$

thus replacing a whole density with a single point, getting rid of the integral and using as

$$\begin{aligned} p(x|\mathcal{X}) &= p(x|\theta_{MAP}) \\ y_{MAP} &= g(x|\theta_{MAP}) \end{aligned}$$

If we have no prior reason to favor some values of θ, then the prior density is flat and the posterior will have the same form as the likelihood, $p(\mathcal{X}|\theta)$, and the MAP estimate will be equivalent to the maximum likelihood estimate (section 4.2) where we have

$$\theta_{ML} = \arg\max_{\theta} p(\mathcal{X}|\theta) \tag{4.15}$$

BAYES' ESTIMATOR

Another possibility is the *Bayes' estimator*, which is defined as the expected value of the posterior density

$$\theta_{Bayes} = E[\theta|\mathcal{X}] = \int \theta p(\theta|\mathcal{X}) d\theta \tag{4.16}$$

The reason for taking the expected value is that the best estimate of a random variable is its mean. Let us say θ is the variable we want to predict with $E[\theta] = \mu$. It can be shown that if c, a constant value, is our estimate of θ, then

$$\begin{aligned} E[(\theta - c)^2] &= E[(\theta - \mu + \mu - c)^2] \\ &= E[(\theta - \mu)^2] + (\mu - c)^2 \end{aligned} \tag{4.17}$$

which is minimum if c is taken as μ. In the case of a normal density, the mode is the expected value and thus if $p(\theta|\mathcal{X})$ is normal, then $\theta_{Bayes} = \theta_{MAP}$.

As an example, let us suppose $x^t \sim \mathcal{N}(\theta, \sigma_0^2)$ and $\theta \sim \mathcal{N}(\mu, \sigma^2)$, where μ, σ, and σ_0^2 are known:

$$\begin{aligned} p(\mathcal{X}|\theta) &= \frac{1}{(2\pi)^{N/2}\sigma_0^N} \exp\left[-\frac{\sum_t (x^t - \theta)^2}{2\sigma_0^2}\right] \\ p(\theta) &= \frac{1}{\sqrt{2\pi}\sigma} \exp\left[-\frac{(\theta - \mu)^2}{2\sigma^2}\right] \end{aligned}$$

It can be shown that $p(\theta|\mathcal{X})$ is normal with

$$E[\theta|\mathcal{X}] = \frac{N/\sigma_0^2}{N/\sigma_0^2 + 1/\sigma^2} m + \frac{1/\sigma^2}{N/\sigma_0^2 + 1/\sigma^2} \mu \tag{4.18}$$

Thus the Bayes' estimator is a weighted average of the prior mean μ and the sample mean m, with weights being inversely proportional to their variances. As the sample size N increases, the Bayes' estimator gets closer to the sample average, using more the information provided by the sample. When σ^2 is small, that is, when we have little prior uncertainty regarding the correct value of θ, or when N is small, our prior guess μ has a higher effect.

Note that both MAP and Bayes' estimators reduce the whole posterior density to a single point and lose information unless the posterior is unimodal and makes a narrow peak around these points. With the cost of computation getting cheaper, one possibility is to use a Monte Carlo approach that generates samples from the posterior density (Andrieu et al. 2003). There also are approximation methods one can use to evaluate the full integral.

4.5 Parametric Classification

We saw in chapter 3 that using the Bayes' rule, we can write the posterior probability of class C_i as

$$P(C_i|x) = \frac{p(x|C_i)P(C_i)}{p(x)} = \frac{p(x|C_i)P(C_i)}{\sum_{k=1}^{K} p(x|C_k)P(C_k)} \tag{4.19}$$

and use the discriminant function

$$g_i(x) = p(x|C_i)P(C_i)$$

or equivalently

$$g_i(x) = \log p(x|C_i) + \log P(C_i) \tag{4.20}$$

If we can assume that $p(x|C_i)$ are Gaussian

$$p(x|C_i) = \frac{1}{\sqrt{2\pi}\sigma_i} \exp\left[-\frac{(x-\mu_i)^2}{2\sigma_i^2}\right] \tag{4.21}$$

equation 4.20 becomes

$$g_i(x) = -\frac{1}{2}\log 2\pi - \log \sigma_i - \frac{(x-\mu_i)^2}{2\sigma_i^2} + \log P(C_i) \tag{4.22}$$

Let us see an example: Assume we are a car company selling K different cars, and for simplicity, let us say that the sole factor that affects a customer's choice is his or her yearly income, which we denote by x. Then $P(C_i)$ is the proportion of customers who buy car type i. If the yearly income distributions of such customers can be approximated with a Gaussian, then $p(x|C_i)$, the probability that a customer who bought car type i has income x, can be taken $\mathcal{N}(\mu_i, \sigma_i^2)$, where μ_i is the mean income of such customers and σ_i^2 is their income variance.

When we do not know $P(C_i)$ and $p(x|C_i)$, we estimate them from a sample and plug in their estimates to get the estimate for the discriminant function. We are given a sample

$$\mathcal{X} = \{x^t, \boldsymbol{r}^t\}_{t=1}^N \tag{4.23}$$

where $x \in \Re$ is one-dimensional and $\boldsymbol{r} \in \{0,1\}^K$ such that

$$r_i^t = \begin{cases} 1 & \text{if } \boldsymbol{x}^t \in C_i \\ 0 & \text{if } \boldsymbol{x}^t \in C_k, k \neq i \end{cases} \tag{4.24}$$

For each class, the estimates for the means and variances are (relying on equation 4.8)

$$m_i = \frac{\sum_t x^t r_i^t}{\sum_t r_i^t} \tag{4.25}$$

$$s_i^2 = \frac{\sum_t (x^t - m_i)^2 r_i^t}{\sum_t r_i^t} \tag{4.26}$$

and the estimates for the priors are (relying on equation 4.6)

$$\hat{P}(C_i) = \frac{\sum_t r_i^t}{N} \tag{4.27}$$

Plugging these estimates into equation 4.22, we get

$$g_i(x) = -\frac{1}{2}\log 2\pi - \log s_i - \frac{(x - m_i)^2}{2s_i^2} + \log \hat{P}(C_i) \tag{4.28}$$

The first term is a constant and can be dropped because it is common in all $g_i(x)$. If the priors are equal, the last term can also be dropped. If we can further assume that variances are equal, we can write

$$g_i(x) = -(x - m_i)^2 \tag{4.29}$$

and thus we assign x to the class with the nearest mean:

Choose C_i if $|x - m_i| = \min_k |x - m_k|$

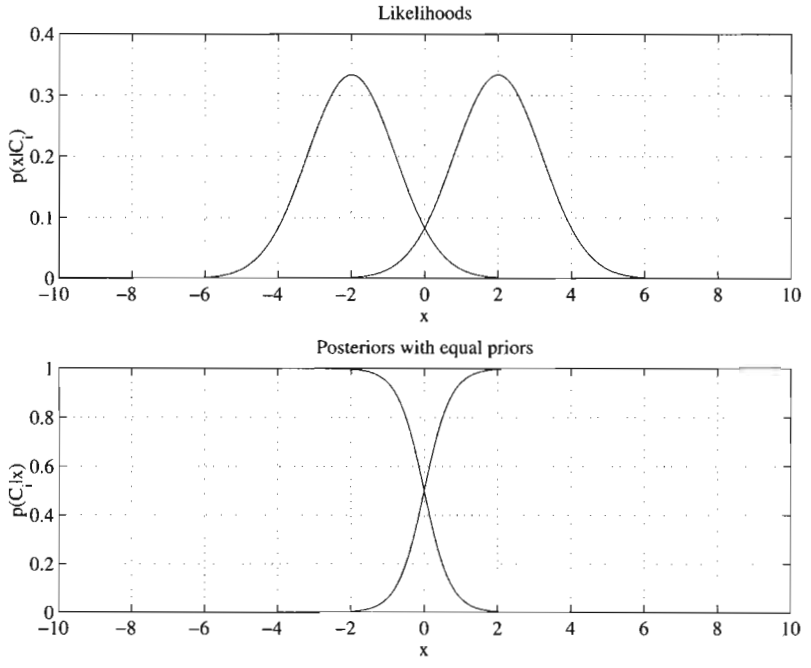

Figure 4.2 Likelihood functions and the posteriors with equal priors for two classes when the input is one-dimensional. Variances are equal and the posteriors intersect at one point, which is the threshold of decision.

With two adjacent classes, the midpoint between the two means is the threshold of decision (see figure 4.2).

$$\begin{aligned} g_1(x) &= g_2(x) \\ (x - m_1)^2 &= (x - m_2)^2 \\ x &= \frac{m_1 + m_2}{2} \end{aligned}$$

When the variances are different, there are two thresholds (see figure 4.3), which can be calculated easily (exercise 4). If the priors are different, this has the effect of moving the threshold of decision toward the mean of the less likely class.

Here we use the maximum likelihood estimators for the parameters but if we have some prior information about them, for example, for the means, we can use a Bayesian estimate of $p(x|C_i)$ with prior on μ_i.

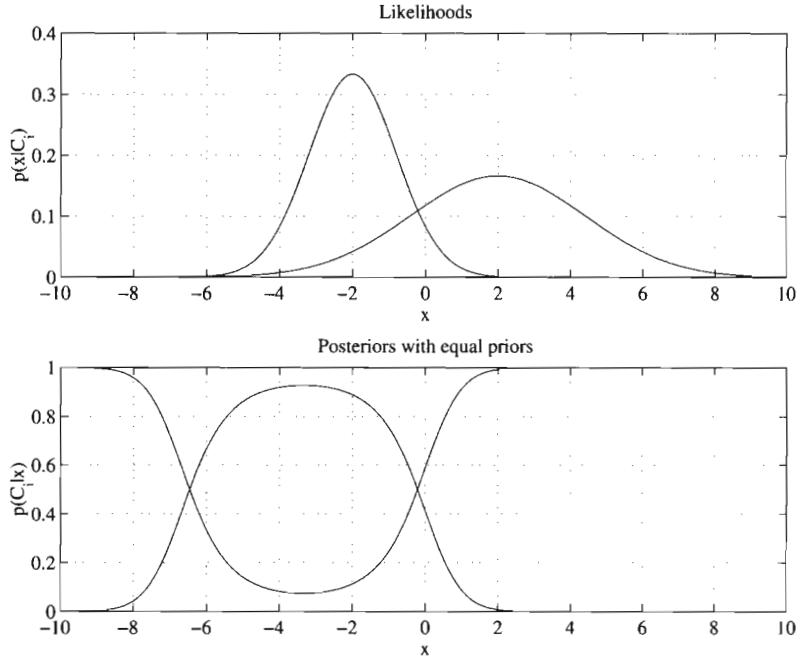

Figure 4.3 Likelihood functions and the posteriors with equal priors for two classes when the input is one-dimensional. Variances are unequal and the posteriors intersect at two points.

One note of caution is necessary here: When x is continuous, we should not immediately rush to use Gaussian densities for $p(x|C_i)$. The classification algorithm—that is, the threshold points—will be wrong if the densities are not Gaussian. In statistical literature, tests exist to check for normality, and such a test should be used before assuming normality. In the case of one-dimensional data, the easiest test is to plot the histogram and to check visually whether the density is bell-shaped, namely, unimodal and symmetric around the center.

This is the *likelihood-based approach* to classification where we use data to estimate the densities, calculate posterior densities using Bayes' rule, and then get the discriminant. In later chapters, we discuss the *discriminant-based approach* where we bypass the estimation of densities and directly estimate the discriminants.

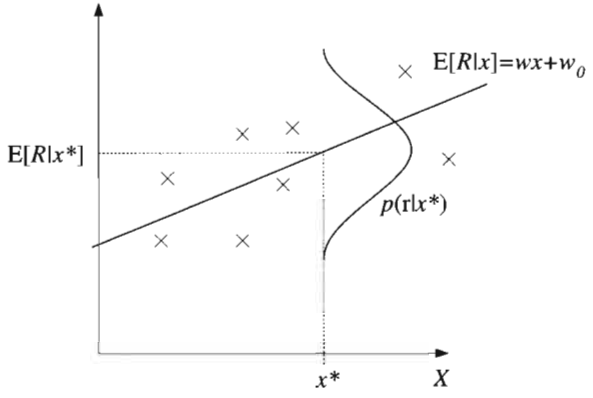

Figure 4.4 Regression assumes 0 mean Gaussian noise added to the model; here, the model is linear.

4.6 Regression

In regression, we would like to write the numeric output, called the *dependent variable,* as a function of the input, called the *independent variable.* We assume that the numeric output is the sum of a deterministic function of the input and random noise:

$$r = f(x) + \epsilon$$

where $f(x)$ is the unknown function, which we would like to approximate by our estimator, $g(x|\theta)$, defined up to a set of parameters θ. If we assume that ϵ is zero mean Gaussian with constant variance σ^2, namely, $\epsilon \sim \mathcal{N}(0, \sigma^2)$, and placing our estimator $g(\cdot)$ in place of the unknown function $f(\cdot)$, we have (figure 4.4)

$$p(r|x) \sim \mathcal{N}(g(x|\theta), \sigma^2) \tag{4.30}$$

We again use maximum likelihood to learn the parameters θ. The pairs (x^t, r^t) in the training set are drawn from an unknown joint probability density $p(x, r)$, which we can write as

$$p(x, r) = p(r|x)p(x)$$

$p(r|x)$ is the probability of the output given the input, and $p(x)$ is the input density. Given an iid sample $\mathcal{X} = \{x^t, r^t\}_{t=1}^N$, the log likelihood is

$$\begin{aligned}\mathcal{L}(\theta|\mathcal{X}) &= \log \prod_{t=1}^{N} p(x^t, r^t) \\ &= \log \prod_{t=1}^{N} p(r^t|x^t) + \log \prod_{t=1}^{N} p(x^t)\end{aligned}$$

We can ignore the second term since it does not depend on our estimator, and we have

$$\begin{aligned}\mathcal{L}(\theta|\mathcal{X}) &= \log \prod_{t=1}^{N} \frac{1}{\sqrt{2\pi}\sigma} \exp\left[-\frac{[r^t - g(x^t|\theta)]^2}{2\sigma^2}\right] \\ &= \log \left(\frac{1}{\sqrt{2\pi}\sigma}\right)^N \exp\left[-\frac{1}{2\sigma^2}\sum_{t=1}^{N}[r^t - g(x^t|\theta)]^2\right] \\ &= -N\log(\sqrt{2\pi}\sigma) - \frac{1}{2\sigma^2}\sum_{t=1}^{N}[r^t - g(x^t|\theta)]^2\end{aligned} \tag{4.31}$$

The first term is independent of the parameters θ and can be dropped, as can the factor $1/\sigma^2$. Maximizing this is equivalent to minimizing

$$E(\theta|\mathcal{X}) = \frac{1}{2}\sum_{t=1}^{N}[r^t - g(x^t|\theta)]^2 \tag{4.32}$$

which is the most frequently used error function, and θ that minimize it are called the *least squares estimates*. This is a transformation frequently done in statistics: When the likelihood l contains exponents, instead of maximizing l, we define an *error function*, $E = -\log l$, and minimize it.

LEAST SQUARES ESTIMATE

LINEAR REGRESSION

In *linear regression*, we have a linear model

$$g(x^t|w_1, w_0) = w_1 x^t + w_0$$

and taking the derivative of the sum of squared errors (equation 4.32), we have two equations in two unknowns

$$\begin{aligned}\sum_t r^t &= N w_0 + w_1 \sum_t x^t \\ \sum_t r^t x^t &= w_0 \sum_t x_t + w_1 \sum_t (x^t)^2\end{aligned}$$

which can be written in vector-matrix form as $\mathbf{A}\boldsymbol{w} = \boldsymbol{y}$ where

$$\mathbf{A} = \begin{bmatrix} N & \sum_t x^t \\ \sum_t x^t & \sum_t (x^t)^2 \end{bmatrix}, \quad \boldsymbol{w} = \begin{bmatrix} w_0 \\ w_1 \end{bmatrix}, \quad \boldsymbol{y} = \begin{bmatrix} \sum_t r^t \\ \sum_t r^t x^t \end{bmatrix}$$

and can be solved as $\mathbf{w} = \mathbf{A}^{-1}\mathbf{y}$.

POLYNOMIAL REGRESSION

In the general case of *polynomial regression*, the model is a polynomial of order k

$$g(x^t|w_k,\ldots,w_2,w_1,w_0) = w_k(x^t)^k + \cdots + w_2(x^t)^2 + w_1x^t + w_0$$

and taking the derivative, we get $k+1$ equations in $k+1$ unknowns, which can be written in vector matrix form $\mathbf{Aw} = \mathbf{y}$ where we have

$$\mathbf{A} = \begin{bmatrix} N & \sum_t x^t & \sum_t (x^t)^2 & \cdots & \sum_t (x^t)^k \\ \sum_t x^t & \sum_t (x^t)^2 & \sum_t (x^t)^3 & \cdots & \sum_t (x^t)^{k+1} \\ \vdots & & & & \\ \sum_t (x^t)^k & \sum_t (x^t)^{k+1} & \sum_t (x^t)^{k+2} & \cdots & \sum_t (x^t)^{2k} \end{bmatrix}$$

$$\mathbf{w} = \begin{bmatrix} w_0 \\ w_1 \\ w_2 \\ \vdots \\ w_k \end{bmatrix}, \mathbf{y} = \begin{bmatrix} \sum_t r^t \\ \sum_t r^t x^t \\ \sum_t r^t (x^t)^2 \\ \vdots \\ \sum_t r^t (x^t)^k \end{bmatrix}$$

We can write $\mathbf{A} = \mathbf{D}^T\mathbf{D}$ and $\mathbf{y} = \mathbf{D}^T\mathbf{r}$ where

$$\mathbf{D} = \begin{bmatrix} 1 & x^1 & (x^1)^2 & \cdots & (x^1)^k \\ 1 & x^2 & (x^2)^2 & \cdots & (x^2)^k \\ \vdots & & & & \\ 1 & x^N & (x^N)^2 & \cdots & (x^N)^k \end{bmatrix}, \mathbf{r} = \begin{bmatrix} r^1 \\ r^2 \\ \vdots \\ r^N \end{bmatrix}$$

and we can then solve for the parameters as

$$\mathbf{w} = (\mathbf{D}^T\mathbf{D})^{-1}\mathbf{D}^T\mathbf{r} \tag{4.33}$$

Assuming Gaussian distributed error and maximizing likelihood corresponds to minimizing the sum of squared errors. Another measure is the *relative square error* (RSE)

RELATIVE SQUARE ERROR

$$E_{RSE} = \frac{\sum_t [r^t - g(x^t|\theta)]^2}{\sum_t (r^t - \bar{r})^2} \tag{4.34}$$

If E_{RSE} is close to 1, then our prediction is as good as predicting by the average; as it gets closer to 0, we have better fit.

Remember that for best generalization, we should adjust the complexity of our learner model to the complexity of the data. In polynomial

regression, the complexity parameter is the order of the fitted polynomial, and therefore we need to find a way to choose the best order that minimizes the generalization error, that is, tune the complexity of the model to best fit the complexity of the function inherent in the data.

4.7 Tuning Model Complexity: Bias/Variance Dilemma

Let us say that a sample $\mathcal{X} = \{x^t, r^t\}$ is drawn from unknown joint probability density $p(x, r)$. Using this sample, we construct our estimate $g(\cdot)$. The expected square error (over the joint density) at x can be written as (using equation 4.17)

$$E[(r - g(x))^2|x] = \underbrace{E[(r - E[r|x])^2|x]}_{noise} + \underbrace{(E[r|x] - g(x))^2}_{squared\ error} \tag{4.35}$$

The first term on the right is the variance of r given x; it does not depend on $g(\cdot)$ or $\mathcal{X}$. It is the variance of noise added, σ^2. This is the part of error that can never be removed, no matter what estimator we use. The second term quantifies how much $g(x)$ deviates from the regression function, $E[r|x]$. This does depend on the estimator and the training set. It may be the case that for one sample, $g(x)$ may be a very good fit; and for some other sample, it may make a bad fit. To quantify how well an estimator $g(\cdot)$ is, we average over possible datasets.

The expected value (average over samples $\mathcal{X}$, all of size N and drawn from the same joint density $p(r, x)$) is (using equation 4.11)

$$E_{\mathcal{X}}[(E[r|x] - g(x))^2|x] = \underbrace{(E[r|x] - E_{\mathcal{X}}[g(x)])^2}_{bias} + \underbrace{E_{\mathcal{X}}[(g(x) - E_{\mathcal{X}}[g(x)])^2]}_{variance} \tag{4.36}$$

As we discussed before, bias measures how much $g(x)$ is wrong disregarding the effect of varying samples, and variance measures how much $g(x)$ fluctuate around the expected value, $E[g(x)]$, as the sample varies.

Let us see a didactic example: To estimate the bias and the variance, we generate a number of datasets $\mathcal{X}_i = \{x_i^t, r_i^t\}, i = 1, \ldots, M$, from some known $f(\cdot)$ with added noise, use each dataset to form an estimator $g_i(\cdot)$, and calculate bias and variance. Note that in real life, we cannot do this because we do not know $f(\cdot)$ or the parameters of the added noise. Then $E[g(x)]$ is estimated by the average over $g_i(\cdot)$:

$$\bar{g}(x) = \frac{1}{M} \sum_{i=1}^{M} g_i(x)$$

Estimated bias and variance are

$$\text{Bias}^2(g) = \frac{1}{N}\sum_t [\bar{g}(x^t) - f(x^t)]^2$$

$$\text{Variance}(g) = \frac{1}{NM}\sum_t \sum_i [g_i(x^t) - \bar{g}(x^t)]^2$$

Let us see some models of different complexity: The simplest is a constant fit

$$g_i(x) = 2$$

This has no variance because we do not use the data and all $g_i(x)$ are the same. But the bias is high, unless of course $f(x)$ is close to 2 for all x. If we take the average of r^t in the sample

$$g_i(x) = \sum_t r_i^t / N$$

instead of the constant 2, this decreases the bias because we would expect the average in general to be a better estimate than the constant. But this increases the variance because the different samples $\mathcal{X}_i$ would have different average values. Normally in this case the decrease in bias would be larger than the increase in variance, and error would decrease.

In the context of polynomial regression, an example is given in Figure 4.5. As the order of the polynomial increases, small changes in the dataset cause a greater change in the fitted polynomials; thus variance increases. But a complex model allows a better fit to the underlying function; thus bias decreases (see figure 4.6). This is called the *bias/variance dilemma* and is true for any machine learning system and not only for polynomial regression (Geman, Bienenstock, and Doursat 1992). To decrease bias, the model should be flexible, at the risk of having high variance. If the variance is kept low, we may not be able to make a good fit to data and have high bias. The optimal model is the one that has the best trade-off between the bias and the variance.

BIAS/VARIANCE DILEMMA

If there is bias, this indicates that our model class does not contain the solution; this is *underfitting.* If there is variance, the model class is too general and also learns the noise; this is *overfitting.* If $g(\cdot)$ is of the same hypothesis class with $f(\cdot)$, for example, a polynomial of the same order, we have an unbiased estimator, and estimated bias decreases as the number of models increase. This shows the error-reducing effect of choosing the right model (which we called *inductive bias* in chapter 2—the two uses of "bias" are different but not unrelated). As for variance, it

UNDERFITTING
OVERFITTING

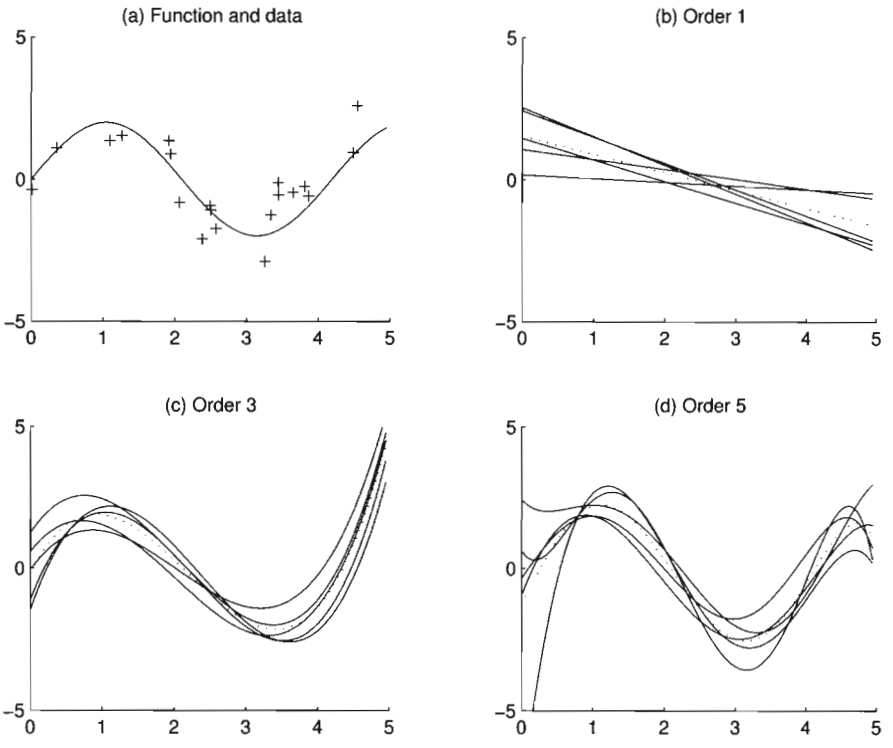

Figure 4.5 (a) Function, $f(x) = 2\sin(1.5x)$, and one noisy ($\mathcal{N}(0,1)$) dataset sampled from the function. Five samples are taken, each containing twenty instances. (b), (c), (d) are five polynomial fits, namely, $g_i(\cdot)$, of order 1, 3, and 5. For each case, dotted line is the average of the five fits, namely, $\overline{g}(\cdot)$.

also depends on the size of the training set; the variability due to sample decreases as the sample size increases. To sum up, to get a small value of error, we should have the proper inductive bias (to get small bias in the statistical sense) and have a large enough dataset so that the variability of the model can be constrained with the data.

Note that when the variance is large, bias is low: This indicates that $\overline{g}(x)$ is a good estimator. So to get a small value of error, we can take a large number of high-variance models and use their average as our estimator. We will discuss such approaches for model combination in chapter 15.

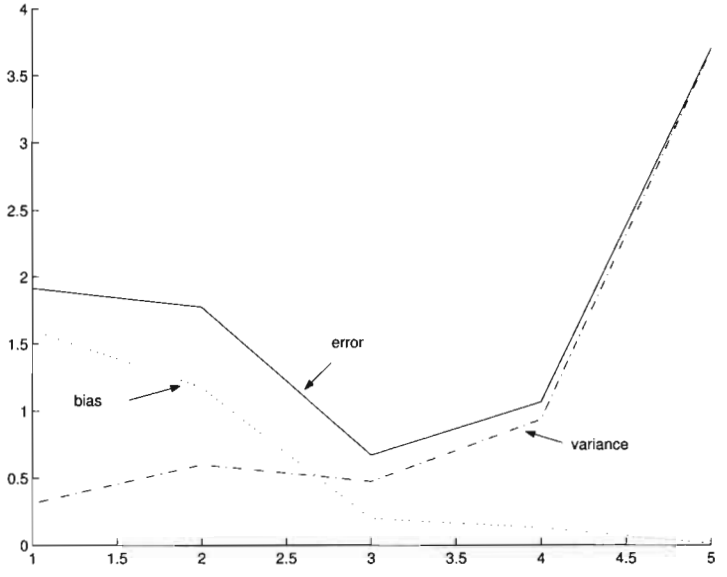

Figure 4.6 In the same setting as that of figure 4.5, using one hundred models instead of five, bias, variance, and error for polynomials of order 1 to 5. Order 1 has the smallest variance. Order 5 has the smallest bias. As the order is increased, bias decreases but variance increases. Order 3 has the minimum error.

4.8 Model Selection Procedures

There are a number of procedures we can use to fine-tune model complexity.

CROSS-VALIDATION

In practice, the method we use to find the optimal complexity is *cross-validation.* We cannot calculate bias and variance for a model, but we can calculate the total error. Given a dataset, we divide it into two parts as training and validation sets, train candidate models of different complexities, and test their error on the validation set left out during training. As the model complexity increases, training error keeps decreasing. The error on the validation set decreases up to a certain level of complexity, then stops decreasing or does not decrease further significantly, or even increases if there is significant noise. This "elbow" corresponds to the optimal complexity level (see figure 4.7).

REGULARIZATION

Another approach that is used frequently is *regularization* (Breiman

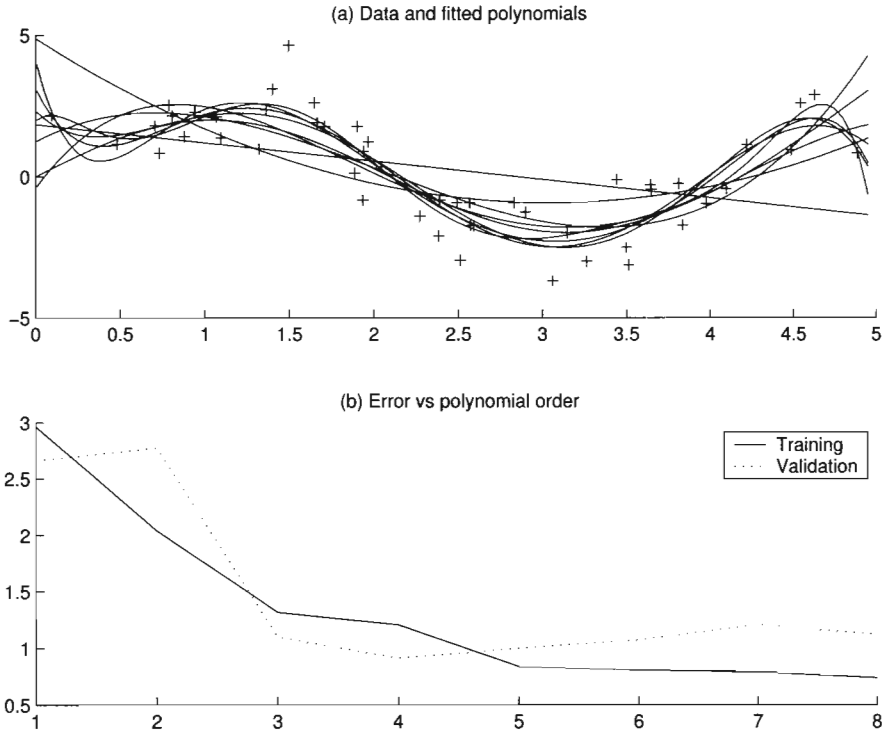

Figure 4.7 In the same setting as that of figure 4.5, training and validation sets (each containing 50 instances) are generated. (a) Training data and fitted polynomials of order from 1 to 8. (b) Training and validation errors as a function of the polynomial order. The "elbow" is at 3.

1998a). In this approach, we write an *augmented error function*

$$E' = \text{error on data} + \lambda \cdot \text{model complexity} \tag{4.37}$$

This has a second term that penalizes complex models with large variance, where λ gives the weight of penalty. When we minimize the augmented error function instead of the error on data only, we penalize complex models and thus decrease variance. If λ is taken too large, only very simple models are allowed and we risk introducing bias. λ is optimized using cross-validation.

STRUCTURAL RISK MINIMIZATION

Structural risk minimization (SRM) (Vapnik 1995) uses a set of models ordered in terms of their complexities. An example is polynomials of in-

creasing order. The complexity is generally given by the number of free parameters. VC dimension is another measure of model complexity. In equation 4.37, we can have a set of decreasing λ_i to get a set of models ordered in increasing complexity. Model selection by SRM then corresponds to finding the model simplest in terms of order and best in terms of empirical error on the data.

MINIMUM DESCRIPTION LENGTH

Minimum description length (MDL) (Rissanen 1978) uses an information theoretic measure. *Kolmogorov complexity* of a dataset is defined as the shortest description of the data. If the data is simple, it has a short complexity; for example, if it is a sequence of '0's, we can just write '0' and the length of the sequence. If the data is completely random, then we cannot have any description of the data shorter than the data itself. If a model is appropriate for the data, then it has a good fit to the data, and instead of the data, we can send/store the model description. Out of all the models that describe the data, we want to have the simplest model so that it lends itself to the shortest description. So we again have a trade-off between how simple the model is and how well it explains the data.

BAYESIAN MODEL SELECTION

Bayesian model selection is used when we have some prior knowledge about the appropriate class of approximating functions. This prior knowledge is defined as a prior distribution over models, $p(\text{model})$. Given the data and assuming a model, we can calculate $p(\text{model}|\text{data})$ using Bayes' rule:

$$p(\text{model}|\text{data}) = \frac{p(\text{data}|\text{model})p(\text{model})}{p(\text{data})} \tag{4.38}$$

$p(\text{model}|\text{data})$ is the posterior probability of the model given our prior subjective knowledge about models, namely, $p(\text{model})$, and the objective support provided by the data, namely, $p(\text{data}|\text{model})$. We can then choose the model with the highest posterior probability, or take an average over all models weighted by their posterior probabilities. When the prior is chosen such that we give higher probabilities to simpler models (following Occam's razor), the Bayesian approach, regularization, SRM, and MDL are equivalent.

Cross-validation is different from all other methods for model selection in that it makes no prior assumption about the model. If there is a large enough validation dataset, it is the best approach. The other models become useful when the data sample is small.

4.9 Notes

A good source on the basics of maximum likelihood and Bayesian estimation is Ross 1987. Many pattern recognition textbooks discuss classification with parametric models (e.g., MacLachlan 1992; Devroye, Györfi, and Lugosi 1996; Webb 1999; Duda, Hart, and Stork 2001). Tests for checking univariate normality can be found in Rencher 1995.

Geman, Bienenstock, and Doursat (1992) discuss bias and variance decomposition for several learning models, which we discuss in later chapters. Bias/variance decomposition is for regression; various researchers proposed different definitions of bias and variance for classification; see Kong and Dietterich 1995 and Breiman 1998b for examples.

4.10 Exercises

1. Write the code that generates a Bernoulli sample with given parameter p, and the code that calculates $\hat{p}$ from the sample.
2. Write the log likelihood for a multinomial sample and show equation 4.6.
3. Write the code that generates a normal sample with given μ and σ, and the code that calculates m and s from the sample. Do the same using the Bayes' estimator assuming a prior distribution for μ.
4. Given two normal distributions $p(x|C_1) \sim \mathcal{N}(\mu_1, \sigma_1^2)$ and $p(x|C_2) \sim \mathcal{N}(\mu_2, \sigma_2^2)$ and $P(C_1)$ and $P(C_2)$, calculate the Bayes' discriminant points analytically.
5. What is the likelihood ratio

   $$\frac{p(x|C_1)}{p(x|C_2)}$$

   in the case of Gaussian densities?
6. For a two-class problem, generate normal samples for two classes with different variances, then use parametric classification to estimate the discriminant points. Compare these with the theoretical values.
7. Assume a linear model and then add 0-mean Gaussian noise to generate a sample. Divide your sample into two as training and validation sets. Use linear regression using the training half. Compute error on the validation set. Do the same for polynomials of degrees 2 and 3 as well.
8. When the training set is small, the contribution of variance to error may be more than that of bias and in such a case, we may prefer a simple model even though we know that it is too simple for the task. Can you give an example?

9. Let us say, given the samples $\mathcal{X}_i = \{x_i^t, r_i^t\}$, we define $g_i(x) = r_i^1$, namely, our estimate for any x is the r value of the first instance in the (unordered) dataset $\mathcal{X}_i$. What can you say about its bias and variance, as compared with $g_i(x) = 2$ and $g_i(x) = \sum_t r_i^t / N$? What if the sample is ordered, so that $g_i(x) = \min_t r_i^t$?

5 Multivariate Methods

In chapter 4, we discussed the parametric approach to classification and regression. Now, we generalize this to the multivariate case where we have multiple inputs and where the output, that is, class code or continuous output, is a function of these multiple inputs. These inputs may be discrete or numeric. We will see how such functions can be learned from a labeled multivariate sample and also how the complexity of the learner can be fine-tuned to the data at hand.

5.1 Multivariate Data

IN MANY APPLICATIONS, several measurements are made on each individual or event generating an observation vector. The sample may be viewed as a *data matrix*

$$\mathbf{X} = \begin{bmatrix} X_1^1 & X_2^1 & \cdots & X_d^1 \\ X_1^2 & X_2^2 & \cdots & X_d^2 \\ \vdots & & & \\ X_1^N & X_2^N & \cdots & X_d^N \end{bmatrix}$$

where the d columns correspond to d *variables* denoting the result of measurements made on an individual or event. These are also called *inputs, features,* or *attributes.* The N rows correspond to independent and identically distributed *observations, examples,* or *instances* on N individuals or events.

INPUT
FEATURE
ATTRIBUTE
OBSERVATION
EXAMPLE
INSTANCE

For example, in deciding on a loan application, an observation vector is the information associated with a customer and is composed of age, marital status, yearly income, and so forth, and we have N such past

customers. These measurements may be of different scales, for example, age in years and yearly income in monetary units. Some like age may be numeric, and some like marital status may be discrete.

Typically these variables are correlated. If they are not, there is no need for a multivariate analysis. Our aim may be *simplification*, that is, summarizing this large body of data by means of relatively few parameters. Or our aim may be *exploratory*, and we may be interested in generating hypotheses about data. In some applications, we are interested in predicting the value of one variable from the values of other variables. If the predicted variable is discrete, this is multivariate classification, and if it is numeric, this is a multivariate regression problem.

5.2 Parameter Estimation

MEAN VECTOR

The *mean vector* $\boldsymbol{\mu}$ is defined such that each of its elements is the mean of one column of $\mathbf{X}$:

$$E[\boldsymbol{x}] = \boldsymbol{\mu} = [\mu_1, \ldots, \mu_d]^T \tag{5.1}$$

The variance of X_i is denoted as σ_i^2, and the covariance of two variables X_i and X_j is defined as

$$\sigma_{ij} \equiv \text{Cov}(X_i, X_j) = E[(X_i - \mu_i)(X_j - \mu_j)] = E[X_i X_j] - \mu_i \mu_j \tag{5.2}$$

with $\sigma_{ij} = \sigma_{ji}$, and when $i = j$, $\sigma_{ii} = \sigma_i^2$. With d variables, there are d variances and $d(d-1)/2$ covariances, which are generally represented as

COVARIANCE MATRIX

a $d \times d$ matrix, named the *covariance matrix*, denoted as $\boldsymbol{\Sigma}$, whose (i, j)th element is σ_{ij}:

$$\boldsymbol{\Sigma} = \begin{bmatrix} \sigma_1^2 & \sigma_{12} & \cdots & \sigma_{1d} \\ \sigma_{21} & \sigma_2^2 & \cdots & \sigma_{2d} \\ \vdots & & & \\ \sigma_{d1} & \sigma_{d2} & \cdots & \sigma_d^2 \end{bmatrix}$$

The diagonal terms are the variances, the off-diagonal terms are the covariances, and the matrix is symmetric. In vector-matrix notation

$$\boldsymbol{\Sigma} \equiv \text{Cov}(\boldsymbol{X}) = E[(\boldsymbol{X} - \boldsymbol{\mu})(\boldsymbol{X} - \boldsymbol{\mu})^T] = E[\boldsymbol{X}\boldsymbol{X}^T] - \boldsymbol{\mu}\boldsymbol{\mu}^T \tag{5.3}$$

If two variables are related in a linear way, then the covariance will be positive or negative depending on whether the relationship has a positive

or negative slope. But the size of the relationship is difficult to interpret because it depends on the units in which the two variables are measured.

CORRELATION

The *correlation* between variables X_i and X_j is a statistic normalized between -1 and $+1$, defined as

$$\text{Corr}(X_i, X_j) \equiv \rho_{ij} = \frac{\sigma_{ij}}{\sigma_i \sigma_j} \tag{5.4}$$

If two variables are independent, then their covariance, and hence their correlation, is zero. However, the converse is not true: The variables may be dependent (in a nonlinear way), and their correlation may be zero.

SAMPLE MEAN

Given a multivariate sample, estimates for these parameters can be calculated: The maximum likelihood estimator for the mean is the *sample mean*, $\mathbf{m}$. Its ith dimension is the average of the ith column of $\mathbf{X}$:

$$\mathbf{m} = \frac{\sum_{t=1}^{N} \mathbf{x}^t}{N} \text{ with } m_i = \frac{\sum_{t=1}^{N} x_i^t}{N}, i = 1, \ldots, d \tag{5.5}$$

SAMPLE COVARIANCE

The estimator of $\mathbf{\Sigma}$ is $\mathbf{S}$, the *sample covariance* matrix, with entries

$$s_i^2 = \frac{\sum_{t=1}^{N} (x_i^t - m_i)^2}{N} \tag{5.6}$$

$$s_{ij} = \frac{\sum_{t=1}^{N} (x_i^t - m_i)(x_j^t - m_j)}{N} \tag{5.7}$$

These are biased estimates, but if in an application the estimates vary significantly depending on whether we divide by N or $N - 1$, we are in serious trouble anyway.

SAMPLE CORRELATION

The *sample correlation* coefficients are

$$r_{ij} = \frac{s_{ij}}{s_i s_j} \tag{5.8}$$

and the sample correlation matrix $\mathbf{R}$ contains r_{ij}.

5.3 Estimation of Missing Values

Frequently values of certain variables may be missing in observations. The best strategy is to discard those observations all together, but generally we do not have large enough samples to be able to afford this and we do not want to lose data as the non-missing entries do contain information. We try to fill in the missing entries by estimating them. This is called *imputation*.

IMPUTATION

In *mean imputation,* for a numeric variable, we substitute the mean (average) of the available data for that variable in the sample. For a discrete variable, we fill in with the most likely value, that is, the value most often seen in the data.

In *imputation by regression,* we try to predict the value of a missing variable from other variables whose values are known for that case. Depending on the type of the missing variable, we define a separate regression or classification problem that we train by the data points for which such values are known. If many different variables are missing, we take the means as the initial estimates and the procedure is iterated until predicted values stabilize. If the variables are not highly correlated, the regression approach is equivalent to mean imputation.

Depending on the context, however, sometimes the fact that a certain attribute value is missing may be important. For example, in a credit card application, if the applicant does not declare his or her telephone number, that may be a critical piece of information. In such cases, this is represented as a separate value to indicate that the value is missing and is used as such.

5.4 Multivariate Normal Distribution

In the multivariate case where $\boldsymbol{x}$ is d-dimensional and normal distributed, we have

$$p(\boldsymbol{x}) = \frac{1}{(2\pi)^{d/2}|\boldsymbol{\Sigma}|^{1/2}} \exp\left[-\frac{1}{2}(\boldsymbol{x}-\boldsymbol{\mu})^T\boldsymbol{\Sigma}^{-1}(\boldsymbol{x}-\boldsymbol{\mu})\right] \tag{5.9}$$

and we write $\boldsymbol{x} \sim \mathcal{N}_d(\boldsymbol{\mu}, \boldsymbol{\Sigma})$ where $\boldsymbol{\mu}$ is the mean vector and $\boldsymbol{\Sigma}$ is the covariance matrix (see figure 5.1). Just as

$$\frac{(x-\mu)^2}{\sigma^2} = (x-\mu)(\sigma^2)^{-1}(x-\mu)$$

is the squared distance from x to μ in standard deviation units, normalizing for different variances, in the multivariate case the *Mahalanobis distance* is used:

MAHALANOBIS DISTANCE

$$(\boldsymbol{x}-\boldsymbol{\mu})^T\boldsymbol{\Sigma}^{-1}(\boldsymbol{x}-\boldsymbol{\mu}) \tag{5.10}$$

$(\boldsymbol{x}-\boldsymbol{\mu})^T\boldsymbol{\Sigma}^{-1}(\boldsymbol{x}-\boldsymbol{\mu}) = c^2$ is the d-dimensional hyperellipsoid centered at $\boldsymbol{\mu}$, and its shape and orientation are defined by $\boldsymbol{\Sigma}$. Because of the use of the inverse of $\boldsymbol{\Sigma}$, if a variable has a larger variance than another, it receives

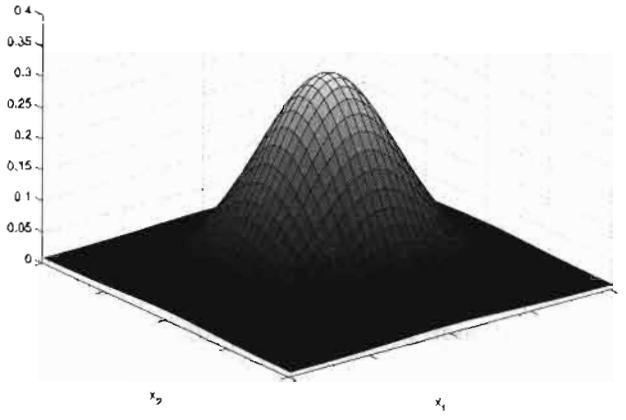

Figure 5.1 Bivariate normal distribution.

less weight in the Mahalanobis distance. Similarly, two highly correlated variables do not contribute as much as two less correlated variables. The use of the inverse of the covariance matrix thus has the effect of standardizing all variables to unit variance and eliminating correlations.

Let us consider the bivariate case where $d = 2$ for visualization purposes (see figure 5.2). When the variables are independent, the major axes of the density are parallel to the input axes. The density becomes an ellipse if the variances are different. The density rotates depending on the sign of the covariance (correlation). The mean vector is $\mu^T = [\mu_1, \mu_2]$, and the covariance matrix is usually expressed as

$$\Sigma = \begin{bmatrix} \sigma_1^2 & \rho\sigma_1\sigma_2 \\ \rho\sigma_1\sigma_2 & \sigma_2^2 \end{bmatrix}$$

The joint bivariate density can be expressed in the form (see exercise 1)

$$p(x_1, x_2) = \frac{1}{2\pi\sigma_1\sigma_2\sqrt{1-\rho^2}} \exp\left[-\frac{1}{2(1-\rho^2)}\left(z_1^2 - 2\rho z_1 z_2 + z_2^2\right)\right] \tag{5.11}$$

where $z_i = (x_i - \mu_i)/\sigma_i, i = 1, 2$, are standardized variables; this is called *z-normalization*. Remember that

Z-NORMALIZATION

$$z_1^2 + 2\rho z_1 z_2 + z_2^2 = \text{constant}$$

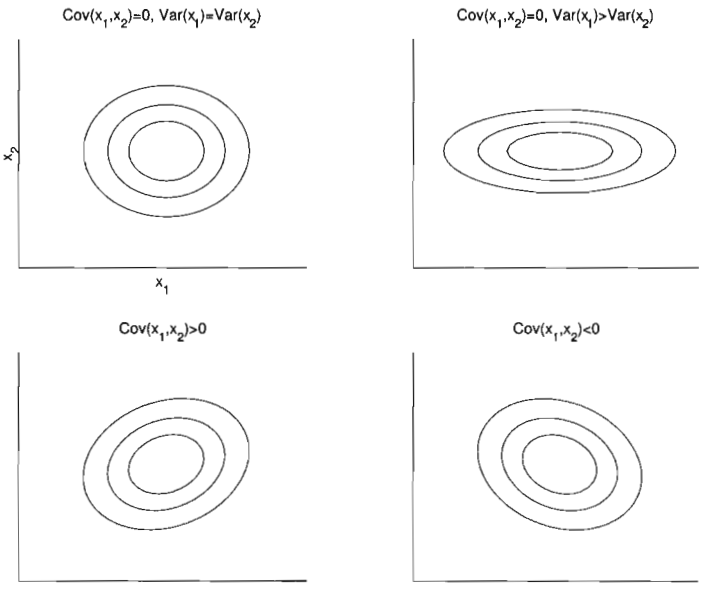

Figure 5.2 Isoprobability contour plot of the bivariate normal distribution. Its center is given by the mean, and its shape and orientation depend on the covariance matrix.

for $|\rho| < 1$, is the equation of an ellipse. When $\rho > 0$, the major axis of the ellipse has a positive slope and if $\rho < 0$, the major axis has a negative slope.

In the expanded Mahalanobis distance of equation 5.11, each variable is normalized to have unit variance, and there is the cross-term that corrects for the correlation between the two variables.

The density depends on five parameters: the two means, the two variances, and the correlation. $\boldsymbol{\Sigma}$ is nonsingular, and hence positive definite, provided that variances are nonzero and $|\rho| < 1$. If ρ is $+1$ or -1, the two variables are linearly related, the observations are effectively one-dimensional, and one of the two variables can be disposed of. If $\rho = 0$, then the two variables are independent, the cross-term disappears, and we get a product of two univariate densities.

In the multivariate case, a small value of $|\boldsymbol{\Sigma}|$ indicates samples are close to $\boldsymbol{\mu}$, just as in the univariate case where a small value of σ^2 indicates samples are close to μ. Small $|\boldsymbol{\Sigma}|$ may also indicate that there is high

correlation between variables. Σ is a symmetric positive definite matrix; this is the multivariate way of saying that $\text{Var}(X) > 0$. If not so, Σ is singular and its determinant is zero. This is either due to linear dependence between the dimensions or because one of the dimensions has zero variance. In such a case, dimensionality should be reduced to a get a positive definite matrix; methods for this are discussed in chapter 6.

If $\mathbf{x} \sim \mathcal{N}_d(\boldsymbol{\mu}, \boldsymbol{\Sigma})$, then each dimension of $\mathbf{x}$ is univariate normal. (The converse is not true: Each X_i may be univariate normal and $\mathbf{X}$ may not be multivariate normal.) Actually any $k < d$ subset of the variables is k-variate normal. A special case is where the components of $\mathbf{x}$ are independent and $\text{Cov}(X_i, X_j) = 0$, for $i \neq j$, and $\text{Var}(X_i) = \sigma_i^2, \forall i$. Then the covariance matrix is diagonal and the joint density is the product of the individual univariate densities:

$$p(\mathbf{x}) = \prod_{i=1}^{d} p_i(x_i) = \frac{1}{(2\pi)^{d/2} \prod_{i=1}^{d} \sigma_i} \exp\left[-\frac{1}{2}\sum_{i=1}^{d}\left(\frac{x_i - \mu_i}{\sigma_i}\right)^2\right] \tag{5.12}$$

Now let us see another property we make use of in later chapters. Let us say $\mathbf{x} \sim \mathcal{N}_d(\boldsymbol{\mu}, \boldsymbol{\Sigma})$ and $\mathbf{w} \in \Re^d$, then

$$\mathbf{w}^T\mathbf{x} = w_1x_1 + w_2x_2 + \cdots + w_dx_d \sim \mathcal{N}(\mathbf{w}^T\boldsymbol{\mu}, \mathbf{w}^T\boldsymbol{\Sigma}\mathbf{w})$$

given that

$$E[\mathbf{w}^T\mathbf{x}] = \mathbf{w}^T E[\mathbf{x}] = \mathbf{w}^T\boldsymbol{\mu} \tag{5.13}$$

$$\begin{aligned}\text{Var}(\mathbf{w}^T\mathbf{x}) &= E[(\mathbf{w}^T\mathbf{x} - \mathbf{w}^T\boldsymbol{\mu})^2] = E[(\mathbf{w}^T\mathbf{x} - \mathbf{w}^T\boldsymbol{\mu})(\mathbf{w}^T\mathbf{x} - \mathbf{w}^T\boldsymbol{\mu})] \\ &= E[\mathbf{w}^T(\mathbf{x} - \boldsymbol{\mu})(\mathbf{x} - \boldsymbol{\mu})^T\mathbf{w}] = \mathbf{w}^T E[(\mathbf{x} - \boldsymbol{\mu})(\mathbf{x} - \boldsymbol{\mu})^T]\mathbf{w}\end{aligned}$$

$$= \mathbf{w}^T\boldsymbol{\Sigma}\mathbf{w} \tag{5.14}$$

That is, the projection of a d-dimensional normal on the vector $\mathbf{w}$ is univariate normal. In the general case, if $\mathbf{W}$ is a $d \times k$ matrix with rank $k < d$, then the k-dimensional $\mathbf{W}^T\mathbf{x}$ is k-variate normal:

$$\mathbf{W}^T\mathbf{x} \sim \mathcal{N}_k(\mathbf{W}^T\boldsymbol{\mu}, \mathbf{W}^T\boldsymbol{\Sigma}\mathbf{W}) \tag{5.15}$$

That is, if we project a d-dimensional normal distribution to a space that is k-dimensional, then it projects to a k-dimensional normal.

5.5 Multivariate Classification

When $\boldsymbol{x} \in \Re^d$, if the class-conditional densities, $p(\boldsymbol{x}|C_i)$, are taken as normal density, $\mathcal{N}_d(\boldsymbol{\mu}_i, \boldsymbol{\Sigma}_i)$, we have

$$p(\boldsymbol{x}|C_i) = \frac{1}{(2\pi)^{d/2}|\boldsymbol{\Sigma}_i|^{1/2}} \exp\left[-\frac{1}{2}(\boldsymbol{x}-\boldsymbol{\mu}_i)^T\boldsymbol{\Sigma}_i^{-1}(\boldsymbol{x}-\boldsymbol{\mu}_i)\right] \tag{5.16}$$

The main reason for this is its analytical simplicity (Duda, Hart, and Stork 2001). Besides, the normal density is a model for many naturally occurring phenomena in that examples of most classes can be seen as mildly changed versions of a single prototype, $\boldsymbol{\mu}_i$, and the covariance matrix, $\boldsymbol{\Sigma}_i$, denotes the amount of noise in each variable and the correlations of these noise sources. While real data may not often be exactly multivariate normal, it is a useful approximation. In addition to its mathematical tractability, the model is robust to departures from normality as is shown in many works (e.g., McLachlan 1992). However, one clear requirement is that the sample of a class should form a single group; if there are multiple groups, one should use a mixture model (chapter 7).

Let us say we want to predict the type of a car that a customer would be interested in. Different cars are the classes and $\boldsymbol{x}$ are observable data of customers, for example, age and income. $\boldsymbol{\mu}_i$ is the vector of mean age and income of customers who buy car type i and $\boldsymbol{\Sigma}_i$ is their covariance matrix: σ_{i1}^2 and σ_{i2}^2 are the age and income variances, and σ_{i12} is the covariance of age and income in the group of customers who buy car type i.

When we define the discriminant function as

$$g_i(\boldsymbol{x}) = \log p(\boldsymbol{x}|C_i) + \log P(C_i)$$

and assuming $p(\boldsymbol{x}|C_i) \sim \mathcal{N}_d(\boldsymbol{\mu}_i, \boldsymbol{\Sigma}_i)$, we have

$$g_i(\boldsymbol{x}) = -\frac{d}{2}\log 2\pi - \frac{1}{2}\log|\boldsymbol{\Sigma}_i| - \frac{1}{2}(\boldsymbol{x}-\boldsymbol{\mu}_i)^T\boldsymbol{\Sigma}_i^{-1}(\boldsymbol{x}-\boldsymbol{\mu}_i) + \log P(C_i) \tag{5.17}$$

Given a training sample for $K \geq 2$ classes, $\mathcal{X} = \{\boldsymbol{x}^t, \boldsymbol{r}^t\}$, where $r_i^t = 1$ if $\boldsymbol{x}^t \in C_i$ and 0 otherwise, estimates for the means and covariances are found using maximum likelihood separately for each class:

$$\begin{aligned} \hat{P}(C_i) &= \frac{\sum_t r_i^t}{N} \\ \boldsymbol{m}_i &= \frac{\sum_t r_i^t \boldsymbol{x}^t}{\sum_t r_i^t} \\ \mathbf{S}_i &= \frac{\sum_t r_i^t (\boldsymbol{x}^t - \boldsymbol{m}_i)(\boldsymbol{x}^t - \boldsymbol{m}_i)^T}{\sum_t r_i^t} \end{aligned} \tag{5.18}$$

These are then plugged into the discriminant function to get the estimates for the discriminants. Ignoring the first constant term, we have

$$g_i(\mathbf{x}) = -\frac{1}{2}\log|\mathbf{S}_i| - \frac{1}{2}(\mathbf{x}-\mathbf{m}_i)^T\mathbf{S}_i^{-1}(\mathbf{x}-\mathbf{m}_i) + \log\hat{P}(C_i) \tag{5.19}$$

Expanding this, we get

$$g_i(\mathbf{x}) = -\frac{1}{2}\log|\mathbf{S}_i| - \frac{1}{2}\left(\mathbf{x}^T\mathbf{S}_i^{-1}\mathbf{x} - 2\mathbf{x}^T\mathbf{S}_i^{-1}\mathbf{m}_i + \mathbf{m}_i^T\mathbf{S}_i^{-1}\mathbf{m}_i\right) + \log\hat{P}(C_i)$$

QUADRATIC DISCRIMINANT

which defines a *quadratic discriminant* (see figure 5.3) that can also be written as

$$g_i(\mathbf{x}) = \mathbf{x}^T\mathbf{W}_i\mathbf{x} + \mathbf{w}_i^T\mathbf{x} + w_{i0} \tag{5.20}$$

where

$$\begin{aligned}\mathbf{W}_i &= -\frac{1}{2}\mathbf{S}_i^{-1}\\ \mathbf{w}_i &= \mathbf{S}_i^{-1}\mathbf{m}_i\\ w_{i0} &= -\frac{1}{2}\mathbf{m}_i^T\mathbf{S}_i^{-1}\mathbf{m}_i - \frac{1}{2}\log|\mathbf{S}_i| + \log\hat{P}(C_i)\end{aligned}$$

The number of parameters to be estimated are $K \cdot d$ for the means and $K \cdot d(d+1)/2$ for the covariance matrices. When d is large and samples are small, $\mathbf{S}_i$ may be singular and inverses may not exist. Or, $|\mathbf{S}_i|$ may be nonzero but too small in which case it will be unstable; small changes in $\mathbf{S}_i$ will cause large changes in $\mathbf{S}_i^{-1}$. For the estimates to be reliable on small samples, one may want to decrease dimensionality, d, by redesigning the feature extractor and select a subset of the features or somehow combine existing features. We discuss such methods in chapter 6.

Another possibility is to pool the data and estimate a common covariance matrix for all classes:

$$\mathbf{S} = \sum_i \hat{P}(C_i)\mathbf{S}_i \tag{5.21}$$

In this case of equal covariance matrices, equation 5.19 reduces to

$$g_i(\mathbf{x}) = -\frac{1}{2}(\mathbf{x}-\mathbf{m}_i)^T\mathbf{S}^{-1}(\mathbf{x}-\mathbf{m}_i) + \log\hat{P}(C_i) \tag{5.22}$$

The number of parameters is $K \cdot d$ for the means and $d(d+1)/2$ for the shared covariance matrix. If the priors are equal, the optimal decision rule is to assign input to the class whose mean's Mahalanobis distance to the input is the smallest. As before, unequal priors shift the boundary

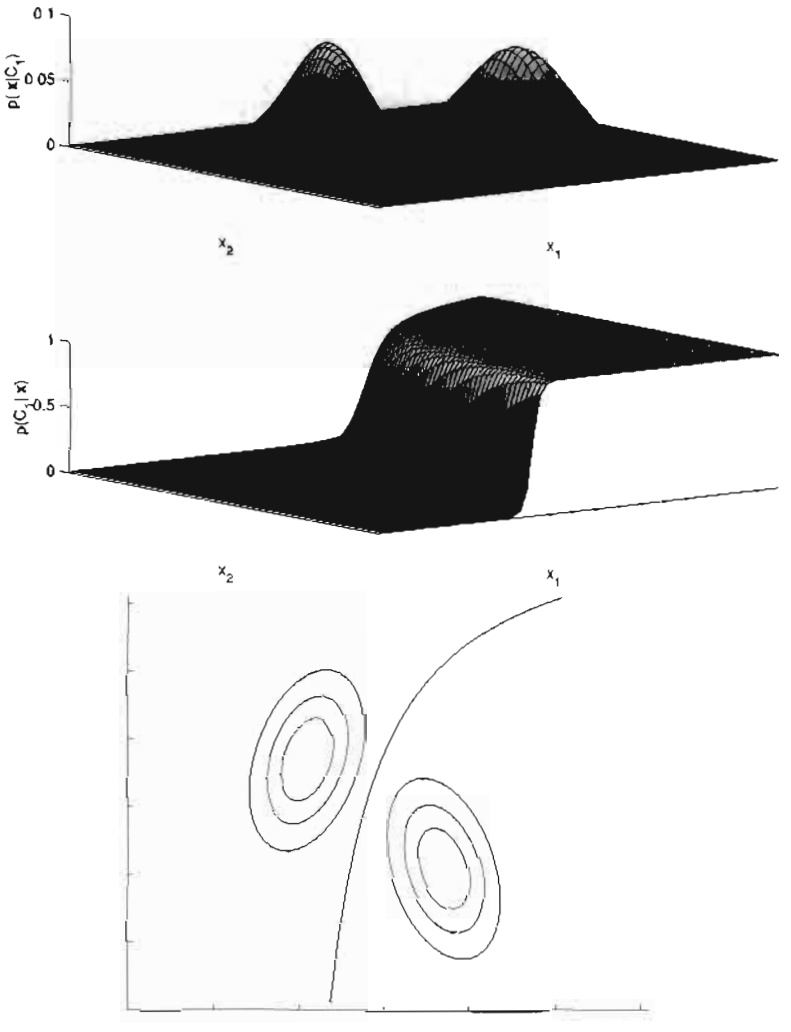

Figure 5.3 Classes have different covariance matrices. Likelihood densities and the posterior probability for one of the classes (top). Class distributions are indicated by isoprobability contours and the discriminant is drawn (bottom).

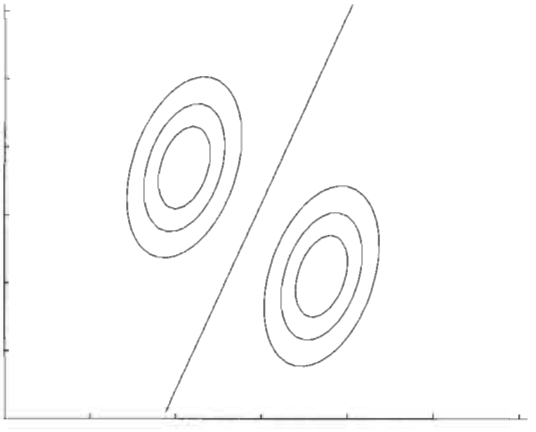

Figure 5.4 Covariances may be arbitary but shared by both classes.

toward the less likely class. Note that in this case, the quadratic term $\boldsymbol{x}^T\mathbf{S}^{-1}\boldsymbol{x}$ cancels since it is common in all discriminants, and the decision boundaries are linear, leading to a *linear discriminant* (figure 5.4) that can be written as

LINEAR DISCRIMINANT

$$g_i(\boldsymbol{x}) = \boldsymbol{w}_i^T\boldsymbol{x} + w_{i0} \tag{5.23}$$

where

$$\begin{aligned} \boldsymbol{w}_i &= \mathbf{S}^{-1}\boldsymbol{m}_i \\ w_{i0} &= -\frac{1}{2}\boldsymbol{m}_i^T\mathbf{S}^{-1}\boldsymbol{m}_i + \log \hat{P}(C_i) \end{aligned}$$

Decision regions of such a linear classifier are convex; namely, when two points are chosen arbitrarily in one decision region and are connected by a straight line, all the points on the line will lie in the region.

Further simplication may be possible by assuming all off-diagonals of the covariance matrix to be zero, thus assuming independent variables. This is the *naive Bayes' classifier* where $p(x_j|C_i)$ are univariate Gaussian. $\mathbf{S}$ and its inverse are diagonal, and we get

NAIVE BAYES' CLASSIFIER

$$g_i(\boldsymbol{x}) = -\frac{1}{2}\sum_{j=1}^{d}\left(\frac{x_j^t - m_{ij}}{s_j}\right)^2 + \log \hat{P}(C_i) \tag{5.24}$$

The term $((x_j^t - m_{ij})/s_j)^2$ has the effect of normalization and measures the distance in terms of standard deviation units. Geometrically speak-

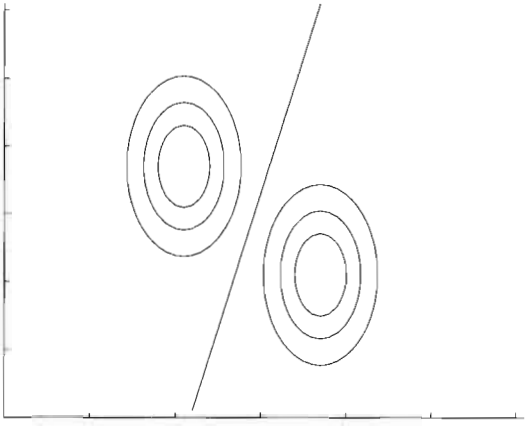

Figure 5.5 All classes have equal, diagonal covariance matrices but variances are not equal.

ing, classes are hyperellipsoidal and, because the covariances are zero, are axis-aligned (see figure 5.5). The number of parameters is $K \cdot d$ for the means and d for the variances. Thus the complexity of $\mathbf{S}$ is reduced from $\mathcal{O}(d^2)$ to $\mathcal{O}(d)$.

EUCLIDEAN DISTANCE

Simplifying even further, if we assume all variances to be equal, the Mahalanobis distance reduces to *Euclidean distance.* Geometrically, the distribution is shaped spherically, centered around the mean vector $\boldsymbol{m}_i$ (see figure 5.6). Then $|\mathbf{S}| = s^{2d}$ and $\mathbf{S}^{-1} = (1/s^2)\mathbf{I}$. The number of parameters in this case is $K \cdot d$ for the means and one for s^2.

$$g_i(\boldsymbol{x}) = -\frac{\|\boldsymbol{x} - \boldsymbol{m}_i\|^2}{2s^2} + \log \hat{P}(C_i) = -\frac{1}{2s^2}\sum_{j=1}^{d}(x_j^t - m_{ij})^2 + \log \hat{P}(C_i) \tag{5.25}$$

NEAREST MEAN CLASSIFIER

TEMPLATE MATCHING

If the priors are equal, we have $g_i(\boldsymbol{x}) = -\|\boldsymbol{x} - \boldsymbol{m}_i\|^2$. This is named the *nearest mean classifier* because it assigns the input to the class of the nearest mean. If each mean is thought of as the ideal prototype or template for the class, this is a *template matching* procedure. This can be expanded as

$$\begin{aligned} g_i(\boldsymbol{x}) &= -\|\boldsymbol{x} - \boldsymbol{m}_i\|^2 = -(\boldsymbol{x} - \boldsymbol{m}_i)^T(\boldsymbol{x} - \boldsymbol{m}_i) \\ &= -(\boldsymbol{x}^T\boldsymbol{x} - 2\boldsymbol{m}_i^T\boldsymbol{x} + \boldsymbol{m}_i^T\boldsymbol{m}_i) \end{aligned} \tag{5.26}$$

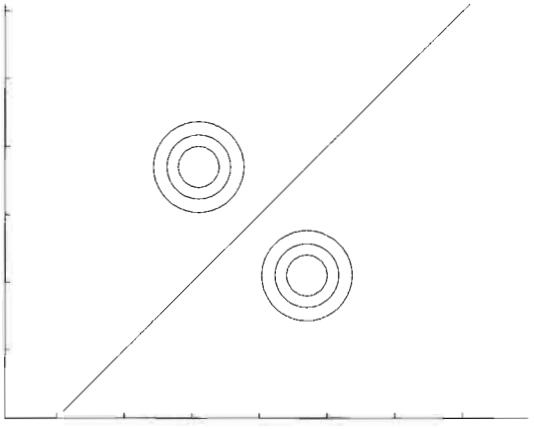

Figure 5.6 All classes have equal, diagonal covariance matrices of equal variances on both dimensions.

The first term, $\mathbf{x}^T\mathbf{x}$, is shared in all $g_i(\mathbf{x})$ and can be dropped, and we can write the discriminant function as

$$g_i(\mathbf{x}) = \mathbf{w}_i^T\mathbf{x} + w_{i0} \tag{5.27}$$

where $\mathbf{w}_i = \mathbf{m}_i$ and $w_{i0} = -(1/2)\|\mathbf{m}_i\|^2$. If all $\mathbf{m}_i$ have similar norms, then this term can also be ignored and we can use

$$g_i(\mathbf{x}) = \mathbf{m}_i^T\mathbf{x} \tag{5.28}$$

When the norms of $\mathbf{m}_i$ are comparable, dot product can also be used as the similarity measure instead of the (negative) Euclidean distance.

We can actually think of finding the best discriminant function as the task of finding the best distance function. This can be seen as another approach to classification: Instead of learning the discriminant functions, $g_i(\mathbf{x})$, we want to learn the suitable distance function $\mathcal{D}(\mathbf{x}_1, \mathbf{x}_2)$, such that for any $\mathbf{x}_1, \mathbf{x}_2, \mathbf{x}_3$, where $\mathbf{x}_1$ and $\mathbf{x}_2$ belong to the same class, and $\mathbf{x}_1$ and $\mathbf{x}_3$ belong to two different classes, we would like to have

$$\mathcal{D}(\mathbf{x}_1, \mathbf{x}_2) < \mathcal{D}(\mathbf{x}_1, \mathbf{x}_3)$$

5.6 Tuning Complexity

In table 5.1, we see how the number of parameters of the covariance matrix may be reduced, trading off the comfort of a simple model with generality. This is another example of bias/variance dilemma. When we make simplifying assumptions about the covariance matrices and decrease the number of parameters to be estimated, we risk introducing bias. On the other hand, if no such assumption is made and the matrices are arbitrary, the quadratic discriminant may have large variance on small datasets. The ideal case depends on the complexity of the problem represented by the data at hand and the amount of data we have. When we have a small dataset, even if the covariance matrices are different, it may be better to assume a shared covariance matrix; a single covariance matrix has fewer parameters and it can be estimated using more data, that is, instances of all classes. This corresponds to using *linear discriminants*, which is very frequently used in classification and which we discuss in more detail in chapter 10.

Note that when we use Euclidean distance to measure similarity, we are assuming that all variables have the same variance and that they are independent. In many cases, this does not hold; for example, age and yearly income are in different units, and are dependent in many contexts. In such a case, the inputs may be separately z-normalized in a preprocessing stage (to have zero mean and unit variance), and then Euclidean distance can be used. On the other hand, sometimes even if the variables are dependent, it may be better to assume that they are independent and to use the naive Bayes' classifier, if we do not have enough data to calculate the dependency accurately.

REGULARIZED DISCRIMINANT ANALYSIS

Friedman (1989) proposed a method that combines all these as special cases, named *regularized discriminant analysis* (RDA). We remember that regularization corresponds to approaches where one starts with high variance and constrains toward lower variance, at the risk of increasing bias. In the case of parametric classification with Gaussian densities, the covariance matrices can be written as a weighted average of the three special cases:

$$\mathbf{S}_i' = \alpha\sigma^2\mathbf{I} + \beta\mathbf{S} + (1 - \alpha - \beta)\mathbf{S}_i \tag{5.29}$$

When $\alpha = \beta = 0$, this leads to a quadratic classifier. When $\alpha = 0$ and $\beta = 1$, the covariance matrices are shared, and we get linear classifiers. When $\alpha = 1$ and $\beta = 0$, the covariance matrices are diagonal with σ^2 on

Table 5.1 Reducing variance through simplifying assumptions.

Assumption	Covariance matrix	No. of parameters
Shared, Hyperspheric	$\mathbf{S}_i = \mathbf{S} = s^2\mathbf{I}$	1
Shared, Axis-aligned	$\mathbf{S}_i = \mathbf{S}$, with $s_{ij} = 0$	d
Shared, Hyperellipsoidal	$\mathbf{S}_i = \mathbf{S}$	$d(d+1)/2$
Different, Hyperellipsoidal	$\mathbf{S}_i$	$K \cdot (d(d+1)/2)$

the diagonals, and we get the nearest mean classifier. In between these extremes, we get a whole variety of classifiers where α, β are optimized by cross-validation.

Another approach to regularization, when the dataset is small, is one that uses a Bayesian approach by defining priors on $\boldsymbol{\mu}_i$ and $\mathbf{S}_i$ or that uses cross-validation to choose the best of the four cases given in table 5.1.

5.7 Discrete Features

In some applications, we have discrete attributes taking one of n different values. For example, an attribute may be color $\in$ {red, blue, green, black}, or another may be pixel $\in$ {on, off}. Let us say x_j are binary (Bernoulli) where

$$p_{ij} \equiv p(x_j = 1|C_i)$$

If x_j are independent binary variables, we have

$$p(\mathbf{x}|C_i) = \prod_{j=1}^{d} p_{ij}^{x_j}(1 - p_{ij})^{(1-x_j)}$$

This is another example of the naive Bayes' classifier where $p(x_j|C_i)$ are Bernoulli. The discriminant function is

$$\begin{aligned} g_i(\mathbf{x}) &= \log p(\mathbf{x}|C_i) + \log P(C_i) \\ &= \sum_j \left[x_j \log p_{ij} + (1 - x_j) \log(1 - p_{ij}) \right] + \log P(C_i) \end{aligned} \tag{5.30}$$

which is linear. The estimator for p_{ij} is

$$\hat{p}_{ij} = \frac{\sum_t x_j^t r_i^t}{\sum_t r_i^t} \tag{5.31}$$

In the general case, let us say we have the multinomial x_j chosen from the set $\{v_1, v_2, \ldots, v_{n_j}\}$. We define new 0/1 dummy variables as

$$z_{jk}^t = \begin{cases} 1 & \text{if } x_j^t = v_k \\ 0 & \text{otherwise} \end{cases}$$

Let p_{ijk} denote the probability that x_j belonging to class C_i takes value v_k.

$$p_{ijk} \equiv p(z_{jk} = 1|C_i) = p(x_j = v_k|C_i)$$

If the attributes are independent, we have

$$p(\mathbf{x}|C_i) = \prod_{j=1}^{d} \prod_{k=1}^{n_j} p_{ijk}^{z_{jk}} \tag{5.32}$$

The discriminant function is then

$$g_i(\mathbf{x}) = \sum_j \sum_k z_{jk} \log p_{ijk} + \log P(C_i) \tag{5.33}$$

The maximum likelihood estimator for p_{ijk} is

$$\hat{p}_{ijk} = \frac{\sum_t z_{jk}^t r_i^t}{\sum_t r_i^t} \tag{5.34}$$

which can be plugged into equation 5.33 to give us the discriminant.

5.8 Multivariate Regression

MULTIVARIATE LINEAR REGRESSION

In *multivariate linear regression,* the numeric output r is assumed to be written as a linear function, that is, a weighted sum, of several input variables, $x_1, \ldots, x_d$, and noise. Actually in statistical literature, this is called *multiple* regression; statisticians use the term *multivariate* when there are multiple outputs. The multivariate linear model is

$$r^t = g(\mathbf{x}^t|w_0, w_1, \ldots, w_d) + \epsilon = w_0 + w_1 x_1^t + w_2 x_2^t + \cdots + w_d x_d^t + \epsilon \tag{5.35}$$

As in the univariate case, we assume ϵ to be normal with mean zero and constant variance, and maximizing the likelihood is equivalent to minimizing the sum of squared errors:

$$E(w_0, w_1, \ldots, w_d|\mathcal{X}) = \frac{1}{2} \sum_t (r^t - w_0 - w_1 x_1^t - w_2 x_2^t - \cdots - w_d x_d^t)^2 \tag{5.36}$$

Taking the derivative with respect to the parameters, $w_j, j = 0, \ldots, d$, we get the *normal equations:*

$$
\begin{aligned}
\sum_t r^t &= N w_0 + w_1 \sum_t x_1^t + w_2 \sum_t x_2^t + \cdots + w_d \sum_t x_d^t \\
\sum_t x_1^t r^t &= w_0 \sum_t x_1^t + w_1 \sum_t (x_1^t)^2 + w_2 \sum_t x_1^t x_2^t + \cdots + w_d \sum_t x_1^t x_d^t \\
\sum_t x_2^t r^t &= w_0 \sum_t x_2^t + w_1 \sum_t x_1^t x_2^t + w_2 \sum_t (x_2^t)^2 + \cdots + w_d \sum_t x_2^t x_d^t \\
&\vdots \\
\sum_t x_d^t r^t &= w_0 \sum_t x_d^t + w_1 \sum_t x_d^t x_1^t + w_2 \sum_t x_d^t x_2^t + \cdots + w_d \sum_t (x_d^t)^2
\end{aligned} \tag{5.37}
$$

Let us define the following vectors and matrix:

$$
\mathbf{X} = \begin{bmatrix} 1 & x_1^1 & x_2^1 & \cdots & x_d^1 \\ 1 & x_1^2 & x_2^2 & \cdots & x_d^2 \\ \vdots & & & & \\ 1 & x_1^N & x_2^N & \cdots & x_d^N \end{bmatrix}, \mathbf{w} = \begin{bmatrix} w_0 \\ w_1 \\ \vdots \\ w_d, \end{bmatrix}, \mathbf{r} = \begin{bmatrix} r^1 \\ r^2 \\ \vdots \\ r^N \end{bmatrix}
$$

Then the normal equations can be written as

$$
\mathbf{X}^T \mathbf{X} \mathbf{w} = \mathbf{X}^T \mathbf{r} \tag{5.38}
$$

and we can solve for the parameters as

$$
\mathbf{w} = (\mathbf{X}^T \mathbf{X})^{-1} \mathbf{X}^T \mathbf{r} \tag{5.39}
$$

This method is the same as we used for polynomial regression using one input. The two problems are the same if we define the variables as $x_1 = x, x_2 = x^2, \ldots, x_k = x^k$. This also gives us a hint as to how we can do *multivariate polynomial regression* if necessary (exercise 5), but unless d is small, in multivariate regression, we rarely use polynomials of an order higher than linear. One advantage of linear models is that after the regression, looking at the $w_j, j = 1, \ldots, d$, values, we can extract knowledge: First, by looking at the signs of w_j, we can see whether x_j have a positive or negative effect on the output. Second, if all x_j are in the same range, by looking at the absolute values of w_j, we can get an idea about how important a feature is, rank the features in terms of their importances, and even remove the features whose w_j are close to zero.

MULTIVARIATE POLYNOMIAL REGRESSION

When there are multiple outputs, this can equivalently be defined as a set of independent single-output regression problems.

5.9 Notes

A good text to brush up on one's knowledge of linear algebra is Strang 1988. Harville 1997 is another excellent book that looks at matrix algebra from a statistical point of view.

One inconvenience with multivariate data is that when the number of dimensions is large, one cannot do a visual analysis. There are methods proposed in the statistical literature for displaying multivariate data; a review is given in Rencher 1995. One possibility is to plot variables two by two as bivariate scatter plots: If the data is multivariate normal, then the plot of any two variables should be roughly linear; this can be used as a visual test of multivariate normality. Another possibility that we discuss in chapter 6 is to project them to one or two dimensions and display there.

Most work on pattern recognition is done assuming multivariate normal densities. Sometimes such a discriminant is even called the Bayes' optimal classifier, but this is generally wrong; it is only optimal if the densities are indeed multivariate normal and if we have enough data to calculate the correct parameters from the data. Rencher 1995 discusses tests for assessing multivariate normality as well as tests for checking for equal covariance matrices. McLachlan 1992 discusses classification with multivariate normals and compares linear and quadratic discriminants.

One obvious restriction of multivariate normals is that it does not allow for data where some features are discrete. A variable with n possible values can be converted into n dummy 0/1 variables, but this increases dimensionality. One can do a dimensionality reduction in this n-dimensional space by a method explained in chapter 6 and thereby not increase dimensionality. Parametric classification for such cases of mixed features is discussed in detail in McLachlan 1992.

5.10 Exercises

1. Show equation 5.11.
2. Generate a sample from a multivariate normal density $\mathcal{N}(\boldsymbol{\mu}, \boldsymbol{\Sigma})$, calculate $\mathbf{m}$ and $\mathbf{S}$, and compare them with $\boldsymbol{\mu}$ and $\boldsymbol{\Sigma}$. Check how your estimates change as the sample size changes.
3. Generate samples from two multivariate normal densities $\mathcal{N}(\boldsymbol{\mu}_i, \boldsymbol{\Sigma}_i), i = 1, 2$, and calculate the Bayes' optimal discriminant for the four cases in table 5.1.

4. For a two-class problem, for the four cases of Gaussian densities in table 5.1, derive

$$\log \frac{P(C_1|\mathbf{x})}{P(C_2|\mathbf{x})}$$

5. Let us say we have two variables x_1 and x_2 and we want to make a quadratic fit using them, namely

$$f(x_1, x_2) = w_0 + w_1 x_1 + w_2 x_2 + w_3 x_1 x_2 + w_4 (x_1)^2 + w_5 (x_2)^2$$

How can we find $w_i, i = 0, \ldots, 5$, given a sample of $\mathcal{X} = \{x_1^t, x_2^t, r^t\}$?

6 *Dimensionality Reduction*

The complexity of any classifier or regressor depends on the number of inputs. This determines both the time and space complexity and the necessary number of training examples to train such a classifier or regressor. In this chapter, we discuss various methods for decreasing input dimensionality without losing accuracy.

6.1 Introduction

IN AN APPLICATION, whether it is classification or regression, observation data that we believe contain information are taken as inputs and fed to the system for decision making. Ideally, we should not need feature selection or extraction as a separate process; the classifier (or regressor) should be able to use whichever features are necessary, discarding the irrelevant. However, there are several reasons why we are interested in reducing dimensionality as a separate preprocessing step:

- In most learning algorithms, the complexity depends on the number of input dimensions, d, as well as on the size of the data sample, N, and for reduced memory and computation, we are interested in reducing the dimensionality of the problem. Decreasing d also decreases the complexity of the inference algorithm during testing.
- When an input is decided to be unnecessary, we save the cost of extracting it.
- Simpler models are more robust on small datasets. Simpler models have less variance, that is, they vary less depending on the particulars of a sample, including noise, outliers, and so forth.

- When data can be explained with fewer features, we get a better idea about the process that underlies the data, which allows knowledge extraction.
- When data can be represented in a few dimensions without loss of information, it can be plotted and analyzed visually for structure and outliers.

FEATURE SELECTION

There are two main methods for reducing dimensionality: feature selection and feature extraction. In *feature selection,* we are interested in finding k of the d dimensions that give us the most information and we discard the other $(d - k)$ dimensions. We are going to discuss *subset selection* as a feature selection method.

FEATURE EXTRACTION

In *feature extraction,* we are interested in finding a new set of k dimensions that are the combination of the original d dimensions. These methods may be supervised or unsupervised depending on whether or not they use the output information. The best known and most widely used feature extraction methods are *Principal Components Analysis* (PCA) and *Linear Discriminant Analysis* (LDA), which are both linear projection methods, unsupervised and supervised respectively. PCA bears much similarity to two other unsupervised linear projection methods, which we also discuss—namely, *Factor Analysis* (FA) and *Multidimensional Scaling* (MDS).

6.2 Subset Selection

SUBSET SELECTION

In *subset selection,* we are interested in finding the best subset of the set of features. The best subset contains the least number of dimensions that most contribute to accuracy. We discard the remaining, unimportant dimensions. Using a suitable error function, this can be used in both regression and classification problems. There are 2^d possible subsets of d variables, but we cannot test for all of them unless d is small and we employ heuristics to get a reasonable (but not optimal) solution in reasonable (polynomial) time.

FORWARD SELECTION

There are two approaches: In *forward selection,* we start with no variables and add them one by one, at each step adding the one that decreases the error the most, until any further addition does not decrease

BACKWARD SELECTION

the error (or decreases it only sightly). In *backward selection,* we start with all variables and remove them one by one, at each step removing

the one that decreases the error the most (or increases it only slightly), until any further removal increases the error significantly. In either case, checking the error should be done on a validation set distinct from the training set because we want to test the generalization accuracy. With more features, generally we have lower training error, but not necessarily lower validation error.

Let us denote by F, a feature set of input dimensions, $x_i, i = 1, \ldots, d$. $E(F)$ denotes the error incurred on the validation sample when only the inputs in F are used. Depending on the application, the error is either the mean square error or misclassification error.

In *sequential forward selection,* we start with no features: $F = \emptyset$. At each step, for all possible x_i, we train our model and calculate $E(F \cup x_i)$ on the validation set. Then, we choose that input x_j that causes the least error

$$j = \arg\min_i E(F \cup x_i) \tag{6.1}$$

and we

$$\text{add } x_j \text{ to } F \text{ if } E(F \cup x_j) < E(F) \tag{6.2}$$

We stop if adding any feature does not decrease E. We may even decide to stop earlier if the decrease in error is too small, where there is a user-defined threshold that depends on the application constraints, trading off the importance of error and complexity. Adding another feature introduces the cost of observing the feature, as well as making the classifier/regressor more complex.

This process may be costly because to decrease the dimensions from d to k, we need to train and test the system $d + (d-1) + (d-2) + \cdots + (d-k)$ times, which is $\mathcal{O}(d^2)$. This is a local search procedure and does not guarantee finding the optimal subset, namely, the minimal subset causing the smallest error. For example, x_i and x_j by themselves may not be good but together may decrease the error a lot, but because this algorithm is greedy and adds attributes one by one, it may not be able to detect this. It is possible to generalize and add m features at a time, instead of one, at the expense of more computation. We can also backtrack and check which previously added feature can be removed after a current addition, thereby increasing the search space but this increases complexity. In *floating search* methods (Pudil, Novovičová, and Kittler 1994), the number of added features and removed features can also change at each step.

FLOATING SEARCH

In *sequential backward selection,* we start with F containing all features and do a similar process except that we remove one attribute from F as opposed to adding to it, and we remove the one that causes the least error

$$j = \arg\min_i E(F - x_i) \tag{6.3}$$

and we

remove x_j from F if $E(F - x_j) < E(F)$ (6.4)

We stop if removing a feature does not decrease the error. To decrease complexity, we may decide to remove a feature if its removal causes only a slight increase in error.

All the variants possible for forward search are also possible for backward search. The complexity of backward search has the same order of complexity as forward search except that training a system with more features is more costly than training a system with fewer features, and forward search may be preferable especially if we expect many useless features.

Subset selection is supervised in that outputs are used by the regressor or classifier to calculate the error, but it can be used with any regression or classification method. In the particular case of multivariate normals for classification, remember that if the original d-dimensional class densities are multivariate normal, then any subset is also multivariate normal and parametric classification can still be used with the advantage of $k \times k$ covariance matrices instead of $d \times d$.

In an application like face recognition, feature selection is not a good method for dimensionality reduction because individual pixels by themselves do not carry much discriminative information; it is the combination of values of several pixels together that carry information about the face identity. This is done by feature extraction methods which we discuss next.

6.3 Principal Components Analysis

In projection methods, we are interested in finding a mapping from the inputs in the original d-dimensional space to a new ($k < d$)-dimensional

space, with minimum loss of information. The projection of $\boldsymbol{x}$ on the direction of $\boldsymbol{w}$ is

$$z = \boldsymbol{w}^T \boldsymbol{x} \tag{6.5}$$

PRINCIPAL COMPONENTS ANALYSIS

Principal components analysis (PCA) is an unsupervised method in that it does not use the output information; the criterion to be maximized is the variance. The principal component is $\boldsymbol{w}_1$ such that the sample, after projection on to $\boldsymbol{w}_1$, is most spread out so that the difference between the sample points becomes most apparent. For a unique solution and to make the direction the important factor, we require $\|\boldsymbol{w}_1\| = 1$. We know from equation 5.14 that if $z_1 = \boldsymbol{w}_1^T \boldsymbol{x}$ with $\text{Cov}(\boldsymbol{x}) = \boldsymbol{\Sigma}$, then

$$\text{Var}(z_1) = \boldsymbol{w}_1^T \boldsymbol{\Sigma} \boldsymbol{w}_1$$

We seek $\boldsymbol{w}_1$ such that $\text{Var}(z_1)$ is maximized subject to the constraint that $\boldsymbol{w}_1^T \boldsymbol{w}_1 = 1$. Writing this as a Lagrange problem, we have

$$\max_{\boldsymbol{w}_1} \boldsymbol{w}_1^T \boldsymbol{\Sigma} \boldsymbol{w}_1 - \alpha(\boldsymbol{w}_1^T \boldsymbol{w}_1 - 1) \tag{6.6}$$

Taking the derivative with respect to $\boldsymbol{w}_1$ and setting it equal to 0, we have

$$2\boldsymbol{\Sigma} \boldsymbol{w}_1 - 2\alpha \boldsymbol{w}_1 = 0, \text{ and therefore } \boldsymbol{\Sigma} \boldsymbol{w}_1 = \alpha \boldsymbol{w}_1$$

which holds if $\boldsymbol{w}_1$ is an eigenvector of $\boldsymbol{\Sigma}$ and α the corresponding eigenvalue. Because we have

$$\boldsymbol{w}_1^T \boldsymbol{\Sigma} \boldsymbol{w}_1 = \alpha \boldsymbol{w}_1^T \boldsymbol{w}_1 = \alpha$$

we choose the eigenvector with the largest eigenvalue for the variance to be maximum. Therefore the principal component is the eigenvector of the covariance matrix of the input sample with the largest eigenvalue, $\lambda_1 = \alpha$.

The second principal component, $\boldsymbol{w}_2$, should also maximize variance, be of unit length, and be orthogonal to $\boldsymbol{w}_1$. This latter requirement is so that after projection $z_2 = \boldsymbol{w}_2^T \boldsymbol{x}$ is uncorrelated with z_1. For the second principal component, we have

$$\max_{\boldsymbol{w}_2} \boldsymbol{w}_2^T \boldsymbol{\Sigma} \boldsymbol{w}_2 - \alpha(\boldsymbol{w}_2^T \boldsymbol{w}_2 - 1) - \beta(\boldsymbol{w}_2^T \boldsymbol{w}_1 - 0) \tag{6.7}$$

Taking the derivative with respect to $\boldsymbol{w}_2$ and setting it equal to 0, we have

$$2\boldsymbol{\Sigma} \boldsymbol{w}_2 - 2\alpha \boldsymbol{w}_2 - \beta \boldsymbol{w}_1 = 0 \tag{6.8}$$

Premultiply by $\boldsymbol{w}_1^T$ and we get

$$2\boldsymbol{w}_1^T\boldsymbol{\Sigma}\boldsymbol{w}_2 - 2\alpha\boldsymbol{w}_1^T\boldsymbol{w}_2 - \beta\boldsymbol{w}_1^T\boldsymbol{w}_1 = 0$$

Note that $\boldsymbol{w}_1^T\boldsymbol{w}_2 = 0$. $\boldsymbol{w}_1^T\boldsymbol{\Sigma}\boldsymbol{w}_2$ is a scalar, equal to its transpose $\boldsymbol{w}_2^T\boldsymbol{\Sigma}\boldsymbol{w}_1$ where, because $\boldsymbol{w}_1$ is the leading eigenvector of $\boldsymbol{\Sigma}$, $\boldsymbol{\Sigma}\boldsymbol{w}_1 = \lambda_1\boldsymbol{w}_1$. Therefore

$$\boldsymbol{w}_1^T\boldsymbol{\Sigma}\boldsymbol{w}_2 = \boldsymbol{w}_2^T\boldsymbol{\Sigma}\boldsymbol{w}_1 = \lambda_1\boldsymbol{w}_2^T\boldsymbol{w}_1 = 0$$

Then $\beta = 0$ and equation 6.8 reduces to

$$\boldsymbol{\Sigma}\boldsymbol{w}_2 = \alpha\boldsymbol{w}_2$$

which implies that $\boldsymbol{w}_2$ should be the eigenvector of $\boldsymbol{\Sigma}$ with the second largest eigenvalue, $\lambda_2 = \alpha$. Similarly, we can show that the other dimensions are given by the eigenvectors with decreasing eigenvalues.

Because $\boldsymbol{\Sigma}$ is symmetric, for two different eigenvalues, the eigenvectors are orthogonal. If $\boldsymbol{\Sigma}$ is positive definite ($\boldsymbol{x}^T\boldsymbol{\Sigma}\boldsymbol{x} > 0$, for all nonnull $\boldsymbol{x}$), then all its eigenvalues are positive. If $\boldsymbol{\Sigma}$ is singular, then its rank, the effective dimensionality, is k with $k < d$ and $\lambda_i, i = k+1, \ldots, d$ are 0 (λ_i are sorted in descending order). The k eigenvectors with nonzero eigenvalues are the dimensions of the reduced space. The first eigenvector (the one with the largest eigenvalue), $\boldsymbol{w}_1$, namely, the principal component, explains the largest part of the variance; the second explains the second largest; and so on.

We define

$$\boldsymbol{z} = \mathbf{W}^T(\boldsymbol{x} - \boldsymbol{m}) \tag{6.9}$$

where the k columns of $\mathbf{W}$ are the k leading eigenvectors of $\mathbf{S}$, the estimator to $\boldsymbol{\Sigma}$. We subtract the sample mean $\boldsymbol{m}$ from $\boldsymbol{x}$ before projection to center the data on the origin. After this linear transformation, we get to a k-dimensional space whose dimensions are the eigenvectors, and the variances over these new dimensions are equal to the eigenvalues (see figure 6.1). To normalize variances, we can divide by the square roots of the eigenvalues.

Let us see another derivation: We want to find a matrix $\mathbf{W}$ such that when we have $\boldsymbol{z} = \mathbf{W}^T\boldsymbol{x}$ (assume without loss of generality that $\boldsymbol{x}$ are already centered), we will get $\text{Cov}(\boldsymbol{z}) = \mathbf{D}'$ where $\mathbf{D}'$ is any diagonal matrix, that is, we would like to get uncorrelated z_i.

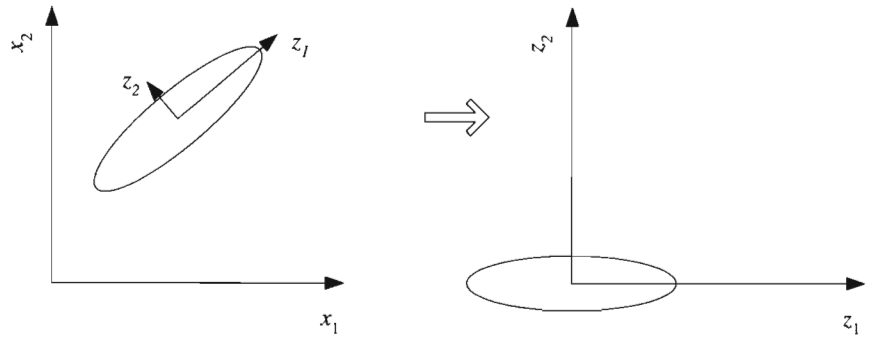

Figure 6.1 Principal components analysis centers the sample and then rotates the axes to line up with the directions of highest variance. If the variance on z_2 is too small, it can be ignored and we have dimensionality reduction from two to one.

If we form a $(d \times d)$ matrix $\mathbf{C}$ whose ith column is the normalized eigenvector $\mathbf{c}_i$ of $\mathbf{S}$, then $\mathbf{C}^T\mathbf{C} = \mathbf{I}$ and

$$\begin{aligned}
\mathbf{S} &= \mathbf{S}\mathbf{C}\mathbf{C}^T \\
&= \mathbf{S}(\mathbf{c}_1, \mathbf{c}_2, \ldots, \mathbf{c}_d)\mathbf{C}^T \\
&= (\mathbf{S}\mathbf{c}_1, \mathbf{S}\mathbf{c}_2, \ldots, \mathbf{S}\mathbf{c}_d)C^T \\
&= (\lambda_1\mathbf{c}_1, \lambda_2\mathbf{c}_2, \ldots, \lambda_d\mathbf{c}_d)\mathbf{C}^T \\
&= \lambda_1\mathbf{c}_1\mathbf{c}_1^T + \cdots + \lambda_d\mathbf{c}_d\mathbf{c}_d^T \\
&= \mathbf{C}\mathbf{D}\mathbf{C}^T \qquad (6.10)
\end{aligned}$$

where $\mathbf{D}$ is a diagonal matrix whose diagonal elements are the eigenvalues, $\lambda_1, \ldots, \lambda_d$. This is called the *spectral decomposition* of $\mathbf{S}$. Since $\mathbf{C}$ is orthogonal and $\mathbf{C}\mathbf{C}^T = \mathbf{C}^T\mathbf{C} = \mathbf{I}$, we can multiply on the left by $\mathbf{C}^T$ and on the right by $\mathbf{C}$ to obtain

SPECTRAL DECOMPOSITION

$$\mathbf{C}^T\mathbf{S}\mathbf{C} = \mathbf{D} \qquad (6.11)$$

We know that if $\mathbf{z} = \mathbf{W}^T\mathbf{x}$, then $\text{Cov}(\mathbf{z}) = \mathbf{W}^T\mathbf{S}\mathbf{W}$, which we would like to be equal to a diagonal matrix. Then from equation 6.11, we see that we can set $\mathbf{W} = \mathbf{C}$.

Let us see an example to get some intuition (Rencher 1995): Assume we are given a class of students with grades on five courses and we want to order these students. That is, we want to project the data onto one

dimension, such that the difference between the data points become most apparent. We can use PCA. The eigenvector with the highest eigenvalue is the direction that has the highest variance, that is, the direction on which the students are most spread out. This works better than taking the average because we take into account correlations and differences in variances.

In practice even if all eigenvalues are greater than zero, if $|\mathbf{S}|$ is small, remembering that $|\mathbf{S}| = \prod_{i=1}^{d} \lambda_i$, we understand that some eigenvalues have little contribution to variance and may be discarded. Then, we take into account the leading k components that explain more than, for example, 90 percent, of the variance. When λ_i are sorted in descending order, the *proportion of variance* explained by the k principal components is

PROPORTION OF VARIANCE

$$\frac{\lambda_1 + \lambda_2 + \cdots + \lambda_k}{\lambda_1 + \lambda_2 + \cdots + \lambda_k + \cdots + \lambda_d}$$

If the dimensions are highly correlated, there will be a small number of eigenvectors with large eigenvalues and k will be much smaller than d and a large reduction in dimensionality may be attained. This is typically the case in many image and speech processing tasks where nearby inputs (in space or time) are highly correlated. If the dimensions are not correlated, k will be as large as d and there is no gain through PCA.

SCREE GRAPH

Scree graph is the plot of variance explained as a function of the number of eigenvectors kept (see figure 6.2). By visually analyzing it, one can also decide on k. At the "elbow," adding another eigenvector does not significantly increase the variance explained.

Another possibility is to ignore the eigenvectors whose eigenvalues are less than the average input variance. Given that $\sum_i \lambda_i = \sum_i s_i^2$ (equal to the *trace* of $\mathbf{S}$, denoted as $\text{tr}(\mathbf{S})$), the average eigenvalue is equal to the average input variance. When we keep only the eigenvectors with eigenvalues greater than the average eigenvalue, we keep only those which have variance higher than the average input variance.

If the variances of the original x_i dimensions vary considerably, they affect the direction of the principal components more than the correlations, so a common procedure is to preprocess the data so that each dimension has 0 mean and unit variance, before using PCA. Or, one may use the eigenvectors of the correlation matrix, $\mathbf{R}$, instead of the covariance matrix, $\mathbf{S}$, for the correlations to be effective and not the individual variances.

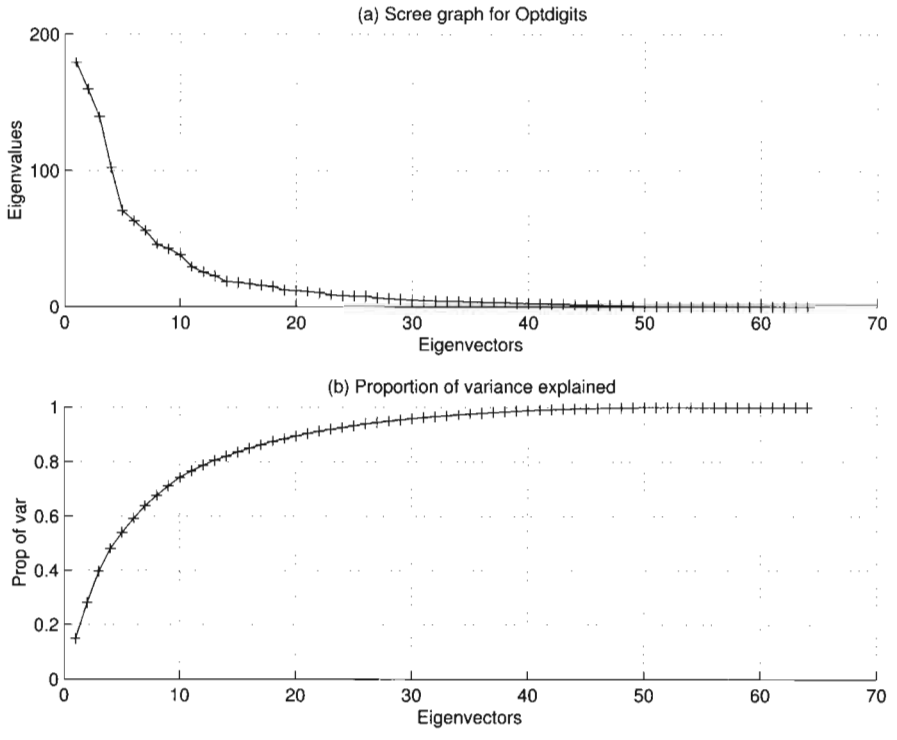

Figure 6.2 (a) Scree graph. (b) Proportion of variance explained is given for the Optdigits dataset from the UCI Repository. This is a handwritten digit dataset with ten classes and sixty-four dimensional inputs. The first twenty eigenvectors explain 90 percent of the variance.

PCA explains variance and is sensitive to outliers: A few points distant from the center would have a large effect on the variances and thus the eigenvectors. *Robust estimation* methods allow calculating parameters in the presence of outliers. A simple method is to calculate the Mahalanobis distance of the data points, discarding the isolated data points that are far away.

If the first two principal components explain a large percentage of the variance, we can do *visual analysis:* We can plot the data in this two dimensional space (figure 6.3) and search visually for structure, groups, outliers, normality, and so forth. This plot gives a better pictorial description of the sample than a plot of any two of the original variables.

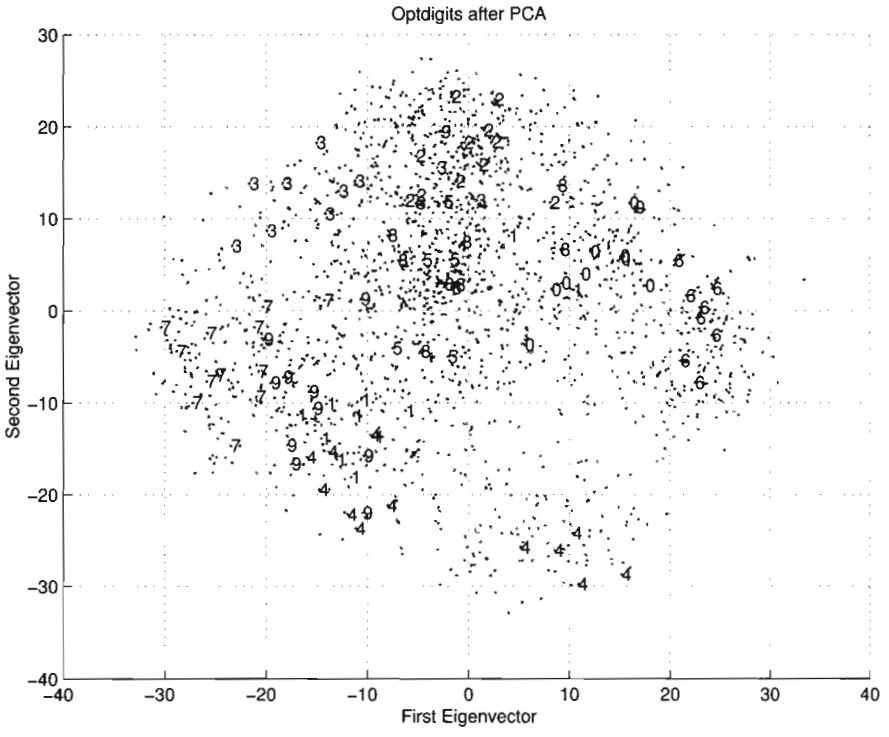

Figure 6.3 Optdigits data plotted in the space of two principal components. Only the labels of hundred data points are shown to minimize the ink-to-noise ratio.

By looking at the dimensions of the principal components, we can also try to recover meaningful underlying variables that describe the data. For example, in image applications where the inputs are images, the eigenvectors can also be displayed as images and can be seen as templates for important features; they are typically named "*eigenfaces*," *eigendigits*," and so forth (Turk and Pentland 1991).

EIGENFACES
EIGENDIGITS

When d is large, calculating, storing, and processing $\mathbf{S}$ may be tedious. It is possible to calculate the eigenvectors and eigenvalues directly from data without explicitly calculating the covariance matrix (Chatfield and Collins 1980).

We know from equation 5.15 that if $\boldsymbol{x} \sim \mathcal{N}_d(\boldsymbol{\mu}, \boldsymbol{\Sigma})$, then after projection $\mathbf{W}^T\boldsymbol{x} \sim \mathcal{N}_k(\mathbf{W}^T\boldsymbol{\mu}, \mathbf{W}^T\boldsymbol{\Sigma}\mathbf{W})$. If the sample contains d-variate normals, then

it projects to k-variate normals allowing us to do parametric discrimination in this hopefully much lower dimensional space. Because z_j are uncorrelated, the new covariance matrices will be diagonal, and if they are normalized to have unit variance, Euclidean distance can be used in this new space, leading to a simple classifier.

Instance $\mathbf{x}^t$ is projected to the z-space as

$$\mathbf{z}^t = \mathbf{W}^T(\mathbf{x}^t - \boldsymbol{\mu})$$

When $\mathbf{W}$ is an orthogonal matrix such that $\mathbf{W}\mathbf{W}^T = \mathbf{I}$, it can be backprojected to the original space as

$$\hat{\mathbf{x}}^t = \mathbf{W}\mathbf{z}^t + \boldsymbol{\mu}$$

$\hat{\mathbf{x}}^t$ is the reconstruction of $\mathbf{x}^t$ from its representation in the z-space. It is known that among all orthogonal linear projections, PCA minimizes the *reconstruction error,* which is the distance between the instance and its reconstruction from the lower dimensional space:

RECONSTRUCTION ERROR

$$\sum_t \|\hat{\mathbf{x}}^t - \mathbf{x}\|^2 \tag{6.12}$$

The reconstruction error depends on how many of the leading components are taken into account. In a visual recognition application—for example, face recognition—displaying $\hat{\mathbf{x}}^t$ allows a visual check for information loss during PCA.

PCA is unsupervised and does not use output information. It is a one-group procedure. However, in the case of classification, there are multiple groups. *Karhunen-Loève expansion* allows using class information; for example, instead of using the covariance matrix of the whole sample, we can estimate separate class covariance matrices, take their average (weighted by the priors) as the covariance matrix, and use its eigenvectors.

KARHUNEN-LOÈVE EXPANSION

In *common principal components* (Flury 1988), we assume that the principal components are the same for each class whereas the variances of these components differ for different classes:

COMMON PRINCIPAL COMPONENTS

$$\mathbf{S}_i = \mathbf{C}\mathbf{D}_i\mathbf{C}^T$$

This allows pooling data and is a regularization method whose complexity is less than that of a common covariance matrix for all classes, while still allowing differentiation of $\mathbf{S}_i$. A related approach is *flexible discriminant analysis* (Hastie, Tibshirani, and Buja 1994), which does a linear projection to a lower-dimensional space where all features are uncorrelated and then uses a minimum distance classifier.

FLEXIBLE DISCRIMINANT ANALYSIS

6.4 Factor Analysis

In PCA, from the original dimensions $x_i, i = 1, \ldots, d$, we form a new set of variables $\mathbf{z}$ that are linear combinations of x_i:

$$\mathbf{z} = \mathbf{W}^T(\mathbf{x} - \boldsymbol{\mu})$$

FACTOR ANALYSIS
LATENT FACTORS

In *factor analysis* (FA), we assume that there is a set of unobservable, *latent factors* $z_j, j = 1, \ldots, k$, which when acting in combination *generate* $\mathbf{x}$. Thus the direction is opposite that of PCA (see figure 6.4). The goal is to characterize the dependency among the observed variables by means of a smaller number of factors.

Suppose there is a group of variables that have high correlation among themselves and low correlation with all the other variables. Then there may be a single underlying factor that gave rise to these variables. If the other variables can be similarly grouped into subsets, then a few factors can represent these groups of variables. Though factor analysis always partitions the variables into factor clusters, whether the factors mean anything, or really exist, is open to question.

FA, like PCA, is a one-group procedure and is unsupervised. The aim is to model the data in a smaller dimensional space without loss of information. In FA, this is measured as the correlation between variables.

As in PCA, we have a sample $\mathcal{X} = \{\mathbf{x}^t\}_t$ drawn from some unknown probability density with $E[\mathbf{x}] = \boldsymbol{\mu}$ and $\text{Cov}(\mathbf{x}) = \boldsymbol{\Sigma}$. We assume that the factors are unit normals, $E[z_j] = 0, \text{Var}(z_j) = 1$, and are uncorrelated, $\text{Cov}(z_i, z_j) = 0, i \neq j$. To explain what is not explained by the factors, there is an added source for each input which we denote by ϵ_i. It is assumed to be 0 mean, $E[\epsilon_i] = 0$, and have some unknown variance, $\text{Var}(\epsilon_i) = \psi_i$. These specific sources are uncorrelated among themselves, $\text{Cov}(\epsilon_i, \epsilon_j) = 0, i \neq j$, and are also uncorrelated with the factors, $\text{Cov}(\epsilon_i, z_j) = 0, \forall i, j$.

FA assumes that each input dimension, $x_i, i = 1, \ldots, d$, can be written as a weighted sum of the $k < d$ factors, $z_j, j = 1, \ldots, k$, plus the residual term (see figure 6.5):

$$x_i - \mu_i = v_{i1}z_1 + v_{i2}z_2 + \cdots + v_{ik}z_k + \epsilon_i, \forall i = 1, \ldots, d$$

$$x_i - \mu_i = \sum_{j=1}^{k} v_{ij}z_j + \epsilon_i \tag{6.13}$$

This can be written in vector-matrix form as

$$\mathbf{x} - \boldsymbol{\mu} = \mathbf{V}\mathbf{z} + \boldsymbol{\epsilon} \tag{6.14}$$

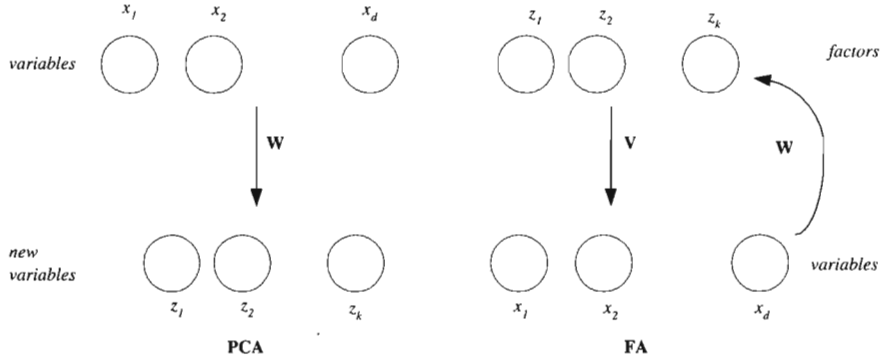

Figure 6.4 Principal components analysis generates new variables that are linear combinations of the original input variables. In factor analysis, however, we posit that there are factors that when linearly combined generate the input variables.

where $\mathbf{V}$ is the $d \times k$ matrix of weights, called *factor loadings*. From now on, we are going to assume that $\boldsymbol{\mu} = \mathbf{0}$ without loss of generality; we can always add $\boldsymbol{\mu}$ after projection. Given that $\text{Var}(z_j) = 1$ and $\text{Var}(\epsilon_i) = \psi_i$

$$\text{Var}(x_i) = v_{i1}^2 + v_{i2}^2 + \cdots + v_{ik}^2 + \psi_i \tag{6.15}$$

$\sum_{j=1}^{k} v_{ij}^2$ is the part of the variance explained by the common factors and ψ_i is the variance specific to x_i.

In vector-matrix form, we have

$$\begin{aligned} \boldsymbol{\Sigma} = \text{Cov}(\boldsymbol{x}) &= \text{Cov}(\mathbf{V}\boldsymbol{z} + \boldsymbol{\epsilon}) \\ &= \text{Cov}(\mathbf{V}\boldsymbol{z}) + \text{Cov}(\boldsymbol{\epsilon}) \\ &= \mathbf{V}\text{Cov}(\boldsymbol{z})\mathbf{V}^T + \boldsymbol{\Psi} \end{aligned} \tag{6.16}$$

$$= \mathbf{V}\mathbf{V}^T + \boldsymbol{\Psi} \tag{6.17}$$

where $\boldsymbol{\Psi}$ is a diagonal matrix with ψ_i on the diagonals. Because the factors are uncorrelated unit normals, we have $\text{Cov}(\boldsymbol{z}) = \mathbf{I}$. With two factors, for example,

$$\text{Cov}(x_1, x_2) = v_{11}v_{21} + v_{12}v_{22}$$

If x_1 and x_2 have high covariance, then they are related through a factor. If it is the first factor, then v_{11} and v_{21} will be both high; if it is the second factor, then v_{12} and v_{22} will be both high. In either case, the sum

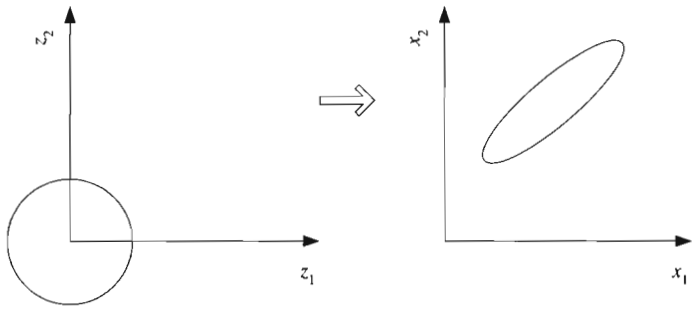

Figure 6.5 Factors are independent unit normals that are stretched, rotated, and translated to make up the inputs.

$v_{11}v_{21} + v_{12}v_{22}$ will be high. If the covariance is low, then x_1 and x_2 depend on different factors and in the products in the sum, one term will be high and the other will be low and the sum will be low.

We see that

$$\text{Cov}(x_1, z_2) = \text{Cov}(v_{12}z_2, z_2) = v_{12}\text{Var}(z_2) = v_{12}$$

Thus $\text{Cov}(\boldsymbol{x}, \boldsymbol{z}) = \mathbf{V}$, and we see that the loadings represent the correlations of variables with the factors.

Given $\mathbf{S}$, the estimator of $\boldsymbol{\Sigma}$, we would like to find $\mathbf{V}$ and $\boldsymbol{\Psi}$ such that

$$\mathbf{S} = \mathbf{V}\mathbf{V}^T + \boldsymbol{\Psi}$$

If there are only a few factors, that is, if $\mathbf{V}$ has few columns, then we have a simplified structure for $\mathbf{S}$, as $\mathbf{V}$ is $d \times k$ and $\boldsymbol{\Psi}$ has d values, thus reducing the number of parameters from d^2 to $d \cdot k + d$.

Since $\boldsymbol{\Psi}$ is diagonal, covariances are represented by $\mathbf{V}$. Note that PCA does not allow a separate $\boldsymbol{\Psi}$ and it tries to account for both the covariances *and* the variances. When all ψ_i are equal, namely, $\boldsymbol{\Psi} = \psi\mathbf{I}$, we get *probabilistic PCA* (Tipping and Bishop 1997) and the conventional PCA is when ψ_i are 0.

PROBABILISTIC PCA

Let us now see how we can find the factor loadings and the specific variances: Let us first ignore $\boldsymbol{\Psi}$. Then, from its spectral decomposition, we know that we have

$$\mathbf{S} = \mathbf{C}\mathbf{D}\mathbf{C}^T = \mathbf{C}\mathbf{D}^{1/2}\mathbf{D}^{1/2}\mathbf{C} = (\mathbf{C}\mathbf{D}^{1/2})(\mathbf{C}\mathbf{D}^{1/2})^T$$

where we take only k of the eigenvectors by looking at the proportion of variance explained so that $\mathbf{C}$ is the $d \times k$ matrix of eigenvectors and $\mathbf{D}^{1/2}$

is the $k \times k$ diagonal matrix with the square roots of the eigenvalues on its diagonals. Thus we have

$$\mathbf{V} = \mathbf{C}\mathbf{D}^{1/2} \tag{6.18}$$

We can find ψ_j from equation 6.15 as

$$\psi_i = s_i^2 - \sum_{j=1}^{k} v_{ij}^2 \tag{6.19}$$

Note that when $\mathbf{V}$ is multiplied with any orthogonal matrix, namely, having the property $\mathbf{T}\mathbf{T}^T = \mathbf{I}$, that is another valid solution and thus the solution is not unique.

$$\mathbf{S} = (\mathbf{V}\mathbf{T})(\mathbf{V}\mathbf{T})^T = \mathbf{V}\mathbf{T}\mathbf{T}^T\mathbf{V}^T = \mathbf{V}\mathbf{I}\mathbf{V}^T = \mathbf{V}\mathbf{V}^T$$

If $\mathbf{T}$ is an orthogonal matrix, the distance to the origin does not change. If $\mathbf{z} = \mathbf{T}\mathbf{x}$, then

$$\mathbf{z}^T\mathbf{z} = (\mathbf{T}\mathbf{x})^T(\mathbf{T}\mathbf{x}) = \mathbf{x}^T\mathbf{T}^T\mathbf{T}\mathbf{x} = \mathbf{x}^T\mathbf{x}$$

Multiplying with an orthogonal matrix has the effect of rotating the axes which allows us to choose the set of axes most interpretable (Rencher 1995). In two dimensions,

$$\mathbf{T} = \begin{pmatrix} \cos\phi & -\sin\phi \\ \sin\phi & \cos\phi \end{pmatrix}$$

rotates the axes by ϕ. There are two types of rotation: In orthogonal rotation the factors are still orthogonal after the rotation, and in oblique rotation the factors are allowed to become correlated. The factors are rotated to give the maximum loading on as few factors as possible for each variable, to make the factors interpretable. However, interpretability is subjective and should not be used to force one's prejudices on the data.

There are two uses of factor analysis: It can be used for knowledge extraction when we find the loadings and try to express the variables using fewer factors. It can also be used for dimensionality reduction when $k < d$. We already saw how the first one is done. Now, let us see how factor analysis can be used for dimensionality reduction.

When we are interested in dimensionality reduction, we need to be able to find the factor scores, z_j, from x_i. We want to find the loadings w_{ji} such that

$$z_j = \sum_{i=1}^{d} w_{ji}x_i + \epsilon_i, j = 1, \ldots, k \tag{6.20}$$

where x_i are centered to have 0 mean. In vector form, for observation t, this can be written as

$$\boldsymbol{z}^t = \mathbf{W}^T\boldsymbol{x}^t + \boldsymbol{\epsilon}, \forall t = 1, \ldots, N$$

This is a linear model with d inputs and k outputs. Its transpose can be written as

$$(\boldsymbol{z}^t)^T = (\boldsymbol{x}^t)^T\mathbf{W} + \boldsymbol{\epsilon}^T, \forall t = 1, \ldots, N$$

Given that we have a sample of N observations, we write

$$\mathbf{Z} = \mathbf{X}\mathbf{W} + \Xi \tag{6.21}$$

where $\mathbf{Z}$ is $N \times k$ of factors, $\mathbf{X}$ is $N \times d$ of (centered) observations, and Ξ is $N \times k$ of zero mean noise. This is multivariate linear regression with multiple outputs, and we know from section 5.8 that $\mathbf{W}$ can be found as

$$\mathbf{W} = (\mathbf{X}^T\mathbf{X})^{-1}\mathbf{X}^T\mathbf{Z}$$

but we do not know $\mathbf{Z}$; it is what we would like to calculate. We multiply and divide both sides by $N - 1$ and obtain

$$\begin{aligned}\mathbf{W} &= (N-1)(\mathbf{X}^T\mathbf{X})^{-1}\frac{\mathbf{X}^T\mathbf{Z}}{N-1} \\ &= \left(\frac{\mathbf{X}^T\mathbf{X}}{N-1}\right)^{-1}\frac{\mathbf{X}^T\mathbf{Z}}{N-1} \\ &= \mathbf{S}^{-1}\mathbf{V} \qquad (6.22)\end{aligned}$$

and placing equation 6.22 in equation 6.21, we write

$$\mathbf{Z} = \mathbf{X}\mathbf{W} = \mathbf{X}\mathbf{S}^{-1}\mathbf{V} \tag{6.23}$$

assuming that $\mathbf{S}$ is nonsingular. One can use $\mathbf{R}$ instead of $\mathbf{S}$ when x_i are normalized to have unit variance.

For dimensionality reduction, FA offers no advantage over PCA except the interpretability of factors allowing the identification of common causes, a simple explanation, and knowledge extraction. For example, in the context of speech recognition, $\boldsymbol{x}$ corresponds to the acoustic signal, but we know that it is the result of the (nonlinear) interaction of a small number of *articulators,* namely, jaw, tongue, velum, lips, and mouth, which are positioned appropriately to shape the air as it comes out of the lungs and generate the speech sound. If a speech signal could be transformed to this articulatory space, then recognition would be much easier. This is one of the current research directions for speech recognition.

6.5 Multidimensional Scaling

Let us say for N points, we are given the distances between pairs of points, $d_{ij}, i, j = 1, \ldots, N$. We do not know the exact coordinates of the points, or their dimensionality, or how the distances are calculated.

MULTIDIMENSIONAL SCALING

Multidimensional scaling (MDS) is the method for placing these points in a low—for example, two-dimensional—space such that the Euclidean distance between them in the two-dimensional space is as close as possible to d_{ij}, the given distances in the original space. Thus it requires a projection from some unknown dimensional space to for example, two dimensions.

In the archetypical example of multidimensional scaling, we take the road travel distances between cities, and after applying MDS, we get an approximation to the map. The map is distorted such that in parts of the country with geographical obstacles like mountains and lakes where the road travel distance deviates much from the direct bird-flight path (Euclidean distance), the map is stretched out to accommodate longer distances (see figure 6.6). The map is centered on the origin, but the solution is still not unique. We can get any rotated or mirror image version.

MDS can be used for dimensionality reduction by calculating pairwise Euclidean distances in the d-dimensional $\mathbf{x}$ space and giving this as input to MDS, which then projects it to a lower-dimensional space so as to preserve these distances.

Let us say we have a sample $\mathcal{X} = \{\mathbf{x}^t\}_{t=1}^N$ as usual, where $\mathbf{x}^t \in \Re^d$. For two points r and s, the squared Euclidean distance between them is

$$\begin{aligned} d_{rs}^2 &= \|\mathbf{x}^r - \mathbf{x}^s\|^2 = \sum_{j=1}^{d} (x_j^r - x_j^s)^2 = \sum_{j=1}^{d} (x_j^r)^2 - 2\sum_{j=1}^{d} x_j^r x_j^s + \sum_{j=1}^{d} (x_j^s)^2 \\ &= b_{rr} + b_{ss} - 2b_{rs} \end{aligned} \tag{6.24}$$

where b_{rs} is defined as

$$b_{rs} = \sum_{j=1}^{d} x_j^r x_j^s \tag{6.25}$$

To constrain the solution, we center the data at the origin and assume

$$\sum_{t=1}^{N} x_j^t = 0, \forall j = 1, \ldots, d$$

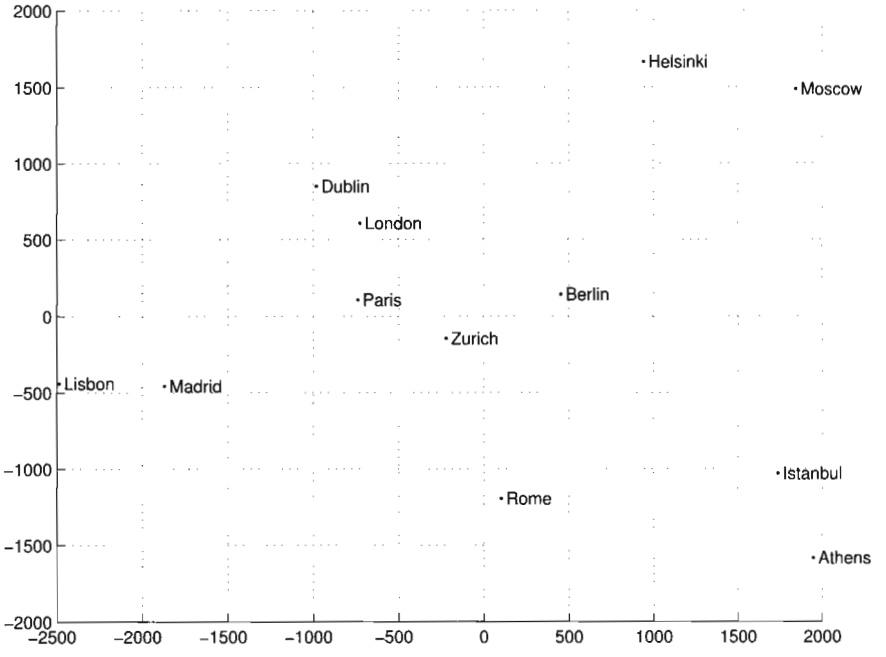

Figure 6.6 Map of Europe drawn by MDS. Cities include Athens, Berlin, Dublin, Helsinki, Istanbul, Lisbon, London, Madrid, Moscow, Paris, Rome, and Zurich. Pairwise road travel distances between these cities are given as input, and MDS places them in two dimensions such that these distances are preserved as well as possible.

Then, summing up equation 6.24 on r, s, and both r, s, and defining

$$T = \sum_{t=1}^{N} b_{tt} = \sum_{t} \sum_{j} (x_j^t)^2$$

we get

$$\begin{aligned} \sum_{r} d_{rs}^2 &= T + N b_{ss} \\ \sum_{s} d_{rs}^2 &= N b_{rr} + T \\ \sum_{r} \sum_{s} d_{rs}^2 &= 2NT \end{aligned}$$

When we define

$$d_{\bullet s}^2 = \frac{1}{N}\sum_r d_{rs}^2 \ , \ d_{r\bullet}^2 = \frac{1}{N}\sum_s d_{rs}^2 \ , \ d_{\bullet\bullet}^2 = \frac{1}{N^2}\sum_r\sum_s d_{rs}^2$$

and using equation 6.24, we get

$$b_{rs} = \frac{1}{2}(d_{r\bullet}^2 + d_{\bullet s}^2 - d_{\bullet\bullet}^2 - d_{rs}^2) \tag{6.26}$$

Having now calculated b_{rs}, and knowing that $\mathbf{B} = \mathbf{X}\mathbf{X}^T$ as defined in equation 6.25, we look for an approximation. We know from the spectral decomposition that $\mathbf{X} = \mathbf{C}\mathbf{D}^{1/2}$ can be used as an approximation for $\mathbf{X}$, where $\mathbf{C}$ is the matrix whose columns are the eigenvectors of $\mathbf{B}$ and $\mathbf{D}^{1/2}$ is a diagonal matrix with square roots of the eigenvalues on the diagonals. Looking at the eigenvalues of $\mathbf{B}$, we decide on a dimensionality k lower than d (and N), as we did in PCA and FA. Let us say $\boldsymbol{c}_j$ are the eigenvectors with λ_j as the corresponding eigenvalues. Note that $\boldsymbol{c}_j$ is N-dimensional. Then we get the new dimensions as

$$z_j^t = \sqrt{\lambda_j} c_j^t, j = 1,\ldots,k, t = 1,\ldots,N \tag{6.27}$$

That is, the new coordinates of instance t are given by the tth elements of the eigenvectors, $\boldsymbol{c}_j, j = 1,\ldots,k$, after normalization.

It has been shown (Chatfield and Collins 1980) that the eigenvalues of $\mathbf{X}\mathbf{X}^T$ $(N \times N)$ are the same as those of $\mathbf{X}^T\mathbf{X}$ $(d \times d)$ and the eigenvectors are related by a simple linear transformation. This shows that PCA does the same work with MDS and does it more cheaply. PCA done on the correlation matrix rather than the covariance matrix equals doing MDS with standardized Euclidean distances where each variable has unit variance.

In the general case, we want to find a mapping $\boldsymbol{z} = \boldsymbol{g}(\boldsymbol{x}|\theta)$, where $\boldsymbol{z} \in \Re^k, \boldsymbol{x} \in \Re^d$, and $\boldsymbol{g}(\boldsymbol{x}|\theta)$ is the mapping function from d to k dimensions defined up to a set of parameters θ. Classical MDS we discussed previously corresponds to a linear transformation

$$\boldsymbol{z} = \boldsymbol{g}(\boldsymbol{x}|\mathbf{W}) = \mathbf{W}^T\boldsymbol{x} \tag{6.28}$$

but in a general case, a nonlinear mapping can also be used; this is called *Sammon mapping*. The normalized error in mapping is called the *Sammon stress* and is defined as

SAMMON MAPPING

$$\begin{aligned} E(\theta|\mathcal{X}) &= \sum_{r,s} \frac{(\|\boldsymbol{z}^r - \boldsymbol{z}^s\| - \|\boldsymbol{x}^r - \boldsymbol{x}^s\|)^2}{\|\boldsymbol{x}^r - \boldsymbol{x}^s\|^2} \\ &= \sum_{r,s} \frac{(\|\boldsymbol{g}(\boldsymbol{x}^r|\theta) - \boldsymbol{g}(\boldsymbol{x}^s|\theta)\| - \|\boldsymbol{x}^r - \boldsymbol{x}^s\|)^2}{\|\boldsymbol{x}^r - \boldsymbol{x}^s\|^2} \end{aligned} \tag{6.29}$$

One can use any regression method for $\boldsymbol{g}(\cdot|\theta)$ and estimate θ to minimize the stress on the training data $\mathcal{X}$. If $\boldsymbol{g}(\cdot)$ is nonlinear in $\boldsymbol{x}$, this will then correspond to a nonlinear dimensionality reduction.

In the case of classification, one can include class information in the distance (see Webb 1999) as

$$d'_{rs} = (1-\alpha)d_{rs} + \alpha c_{rs}$$

where c_{rs} is the "distance" between the classes $\boldsymbol{x}^r$ and $\boldsymbol{x}^s$ belong to. This inter-class distance should be supplied subjectively and α is optimized using cross-validation.

6.6 Linear Discriminant Analysis

LINEAR DISCRIMINANT ANALYSIS

Linear discriminant analysis (LDA) is a supervised method for dimensionality reduction for classification problems. We start with the case where there are two classes, then generalize to $K > 2$ classes.

Given samples from two classes C_1 and C_2, we want to find the direction, as defined by a vector $\boldsymbol{w}$, such that when the data are projected onto $\boldsymbol{w}$, the examples from the two classes are as well separated as possible. As we saw before,

$$z = \boldsymbol{w}^T\boldsymbol{x} \tag{6.30}$$

is the projection of $\boldsymbol{x}$ onto $\boldsymbol{w}$ and thus is a dimensionality reduction from d to 1.

$\boldsymbol{m}_1$ and m_1 are the means of samples from C_1 before and after projection, respectively. Note that $\boldsymbol{m}_1 \in \Re^d$ and $m_1 \in \Re$. We are given a sample $\mathcal{X} = \{\boldsymbol{x}^t, r^t\}$ such that $r^t = 1$ if $\boldsymbol{x}^t \in C_1$ and $r^t = 0$ if $\boldsymbol{x}^t \in C_2$.

$$\begin{aligned} m_1 &= \frac{\sum_t \boldsymbol{w}^T\boldsymbol{x}^t r^t}{\sum_t r^t} = \boldsymbol{w}^T\boldsymbol{m}_1 \\ m_2 &= \frac{\sum_t \boldsymbol{w}^T\boldsymbol{x}_t(1-r^t)}{\sum_t (1-r^t)} = \boldsymbol{w}^T\boldsymbol{m}_2 \end{aligned} \tag{6.31}$$

SCATTER

The *scatter* of samples from C_1 and C_2 after projection are

$$\begin{aligned} s_1^2 &= \sum_t (\boldsymbol{w}^T\boldsymbol{x}^t - m_1)^2 r^t \\ s_2^2 &= \sum_t (\boldsymbol{w}^T\boldsymbol{x}^t - m_2)^2 (1-r^t) \end{aligned} \tag{6.32}$$

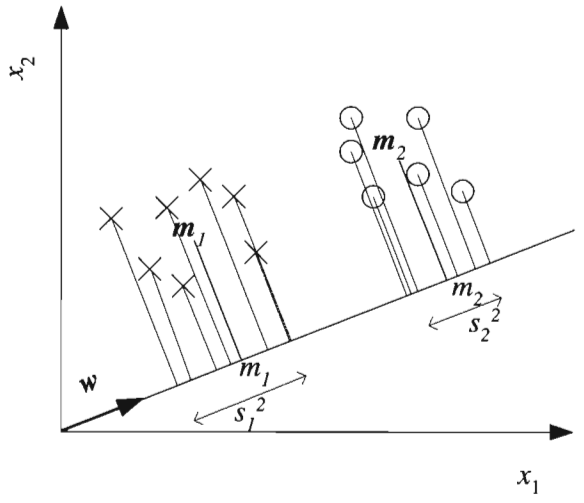

Figure 6.7 Two-dimensional, two-class data projected on $\mathbf{w}$.

After projection, for the two classes to be well separated, we would like the means to be as far apart as possible and the examples of classes be scattered in as small a region as possible. So we want $|m_1 - m_2|$ to be large and $s_1^2 + s_2^2$ to be small (see figure 6.7). *Fisher's linear discriminant* is $\mathbf{w}$ that maximizes

FISHER'S LINEAR DISCRIMINANT

$$J(\mathbf{w}) = \frac{(m_1 - m_2)^2}{s_1^2 + s_2^2} \tag{6.33}$$

Rewriting the numerator, we get

$$\begin{aligned}(m_1 - m_2)^2 &= (\mathbf{w}^T\mathbf{m}_1 - \mathbf{w}^T\mathbf{m}_2)^2 \\ &= \mathbf{w}^T(\mathbf{m}_1 - \mathbf{m}_2)(\mathbf{m}_1 - \mathbf{m}_2)^T\mathbf{w} \\ &= \mathbf{w}^T\mathbf{S}_B\mathbf{w} \end{aligned} \tag{6.34}$$

BETWEEN-CLASS SCATTER MATRIX

where $\mathbf{S}_B = (\mathbf{m}_1 - \mathbf{m}_2)(\mathbf{m}_1 - \mathbf{m}_2)^T$ is the *between-class scatter matrix*. The denominator is the sum of scatter of examples of classes around their means after projection and can be rewritten as

$$\begin{aligned}s_1^2 &= \sum_t (\mathbf{w}^T\mathbf{x}^t - m_1)^2 r^t \\ &= \sum_t \mathbf{w}^T(\mathbf{x}^t - \mathbf{m}_1)(\mathbf{x}^t - \mathbf{m}_1)^T\mathbf{w}r^t\end{aligned}$$

$$= \boldsymbol{w}^T \mathbf{S}_1 \boldsymbol{w} \tag{6.35}$$

where

$$\mathbf{S}_1 = \sum_t r^t (\boldsymbol{x}^t - \boldsymbol{m}_1)(\boldsymbol{x}^t - \boldsymbol{m}_1)^T \tag{6.36}$$

WITHIN-CLASS SCATTER MATRIX

is the *within-class scatter matrix* for C_1. $\mathbf{S}_1 / \sum_t r^t$ is the estimator of $\boldsymbol{\Sigma}_1$. Similarly $s_2^2 = \boldsymbol{w}^T \mathbf{S}_2 \boldsymbol{w}$ with $\mathbf{S}_2 = \sum_t (1 - r^t)(\boldsymbol{x}^t - \boldsymbol{m}_2)(\boldsymbol{x}^t - \boldsymbol{m}_2)^T$, and we get

$$s_1^2 + s_2^2 = \boldsymbol{w}^T \mathbf{S}_W \boldsymbol{w}$$

where $\mathbf{S}_W = \mathbf{S}_1 + \mathbf{S}_2$ is the total within class scatter. Note that $s_1^2 + s_2^2$ divided by the total number of samples is the variance of the pooled data. Equation 6.33 can be rewritten as

$$J(\boldsymbol{w}) = \frac{\boldsymbol{w}^T \mathbf{S}_B \boldsymbol{w}}{\boldsymbol{w}^T \mathbf{S}_W \boldsymbol{w}} = \frac{|\boldsymbol{w}^T (\boldsymbol{m}_1 - \boldsymbol{m}_2)|^2}{\boldsymbol{w}^T \mathbf{S}_W \boldsymbol{w}} \tag{6.37}$$

Taking the derivative of J with respect to $\boldsymbol{w}$ and setting it equal to 0, we get

$$\frac{\boldsymbol{w}^T (\boldsymbol{m}_1 - \boldsymbol{m}_2)}{\boldsymbol{w}^T \mathbf{S}_W \boldsymbol{w}} \left(2(\boldsymbol{m}_1 - \boldsymbol{m}_2) - \frac{\boldsymbol{w}^T (\boldsymbol{m}_1 - \boldsymbol{m}_2)}{\boldsymbol{w}^T \mathbf{S}_W \boldsymbol{w}} \mathbf{S}_W \boldsymbol{w} \right) = 0$$

Given that $\boldsymbol{w}^T (\boldsymbol{m}_1 - \boldsymbol{m}_2) / \boldsymbol{w}^T \mathbf{S}_W \boldsymbol{w}$ is a constant, we have

$$\boldsymbol{w} = c \mathbf{S}_W^{-1} (\boldsymbol{m}_1 - \boldsymbol{m}_2) \tag{6.38}$$

where c is some constant. Because it is the direction that is important for us and not the magnitude, we can just take $c = 1$ and find $\boldsymbol{w}$.

Remember that when $p(\boldsymbol{x}|C_i) \sim \mathcal{N}(\boldsymbol{\mu}_i, \boldsymbol{\Sigma})$, we have a linear discriminant where $\boldsymbol{w} = \boldsymbol{\Sigma}^{-1}(\boldsymbol{\mu}_1 - \boldsymbol{\mu}_2)$, and we see that Fisher's linear discriminant is optimal if the classes are normally distributed. Under the same assumption, a threshold, w_0, can also be calculated to separate the two classes. But Fisher's linear discriminant can be used even when the classes are not normal. We have projected the samples from d dimensions to one, and any classification method can be used afterward.

In the case of $K > 2$ classes, we want to find the matrix $\mathbf{W}$ such that

$$\boldsymbol{z} = \mathbf{W}^T \boldsymbol{x} \tag{6.39}$$

where $\boldsymbol{z}$ is k-dimensional and $\mathbf{W}$ is $d \times k$. The within-class scatter matrix for C_i is

$$\mathbf{S}_i = \sum_t r_i^t (\boldsymbol{x}^t - \boldsymbol{m}_i)(\boldsymbol{x}^t - \boldsymbol{m}_i)^T \tag{6.40}$$

where $r_i^t = 1$ if $\mathbf{x}^t \in C_i$ and 0 otherwise. The total within-class scatter is

$$\mathbf{S}_W = \sum_{i=1}^{K} \mathbf{S}_i \tag{6.41}$$

When there are $K > 2$ classes, the scatter of the means is calculated as how much they are scattered around the overall mean

$$\mathbf{m} = \frac{1}{K} \sum_{i=1}^{K} \mathbf{m}_i \tag{6.42}$$

and the between-class scatter matrix is

$$\mathbf{S}_B = \sum_{i=1}^{K} N_i (\mathbf{m}_i - \mathbf{m})(\mathbf{m}_i - \mathbf{m})^T \tag{6.43}$$

with $N_i = \sum_t r_i^t$. The between-class scatter matrix after projection is $\mathbf{W}^T \mathbf{S}_B \mathbf{W}$ and the within-class scatter matrix after projection is $\mathbf{W}^T \mathbf{S}_W \mathbf{W}$. These are both $k \times k$ matrices. We want the first scatter to be large, that is, after the projection, in the new k-dimensional space we want class means to be as far apart from each other as possible. We want the second scatter to be small, that is, after the projection, we want samples from the same class to be as close to their mean as possible. For a scatter (or covariance) matrix, a measure of spread is the determinant, remembering that the determinant is the product of eigenvalues and that an eigenvalue gives the variance along its eigenvector (component). Thus we are interested in the matrix $\mathbf{W}$ that maximizes

$$J(\mathbf{W}) = \frac{|\mathbf{W}^T \mathbf{S}_B \mathbf{W}|}{|\mathbf{W}^T \mathbf{S}_W \mathbf{W}|} \tag{6.44}$$

The largest eigenvectors of $\mathbf{S}_W^{-1} \mathbf{S}_B$ are the solution. $\mathbf{S}_B$ is the sum of K matrices of rank 1, namely, $(\mathbf{m}_i - \mathbf{m})(\mathbf{m}_i - \mathbf{m})^T$, and only $K - 1$ of them are independent. Therefore, $\mathbf{S}_B$ has a maximum rank of $K - 1$ and we take $k = K - 1$. Thus we define a new lower, $(K - 1)$-dimensional space where the discriminant is then to be constructed (see figure 6.8). Though LDA uses class separability as its goodness criterion, any classification method can be used in this new space for estimating the discriminants.

6.7 Notes

A survey of feature selection algorithms is given in Devijer and Kittler 1982. Subset selection in regression is discussed in Miller 1990. The for-

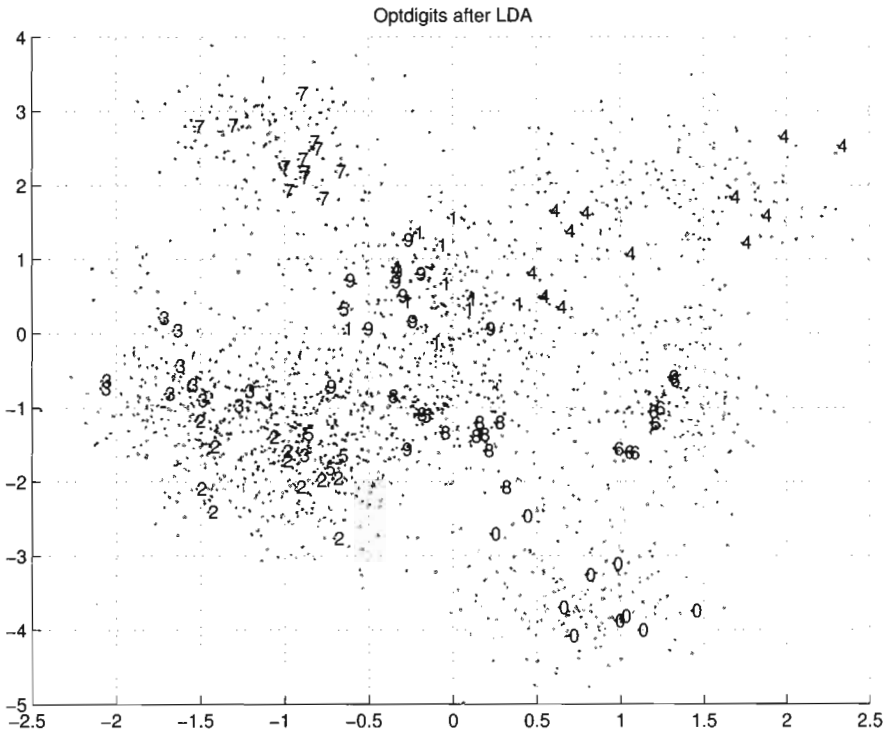

Figure 6.8 Optdigits data plotted in the space of the first two dimensions found by LDA. Comparing this with figure 6.3, we see that LDA, as expected, leads to a better separation of classes than PCA. Even in this two-dimensional space (there are nine), we can discern separate clouds for different classes.

ward and backward search procedures we discussed are local search procedures. Fukunaga and Narendra (1977) proposed a branch and bound procedure. At considerably more expense, one can use a stochastic procedure like simulated annealing or genetic algorithms to search more widely in the the search space. In the case of classification, instead of training a classifier and testing it at each step, one can use heuristics, like the one used in linear discriminant analysis, to measure the quality of the new space in separating classes from each other (McLachlan 1992).

Projection methods work with numeric inputs, and discrete variables should be represented by 0/1 dummy variables, whereas subset selection can use discrete inputs directly. Finding the eigenvectors and eigenvalues

is quite straightforward; an example of a code is given in Press et al. 1992. Factor analysis was introduced by the British psychologist Charles Spearman to find the single factor for intelligence which explains the correlation between scores on various intelligence tests. The existence of such a single factor, called g, is subject to discussion. More information on multidimensional scaling can be found in Cox and Cox 1994.

The projection methods we discussed are batch procedures in that they require that the whole sample be given before the projection directions are found. Mao and Jain (1995) discuss online procedures for doing PCA and LDA, where instances are given one by one and updates are done as new instances arrive.

PRINCIPAL CURVES

The linear projection methods discussed in this chapter have a limited scope. In many applications, features interract in a nonlinear manner, requiring nonlinear feature extraction methods. *Principal curves* (Hastie and Stuetzle 1989) allow a nonlinear projection and find a smooth curve, as opposed to a line, that passes through the "middle" of a group of data. Another possibility in doing a nonlinear projection is when the estimator in Sammon mapping is taken as a nonlinear function, for example, a multilayer perceptron (section 11.11) (Mao and Jain 1995). It is also possible but much harder to do nonlinear factor analysis. When the models are nonlinear, it is difficult to come up with the right nonlinear model. One also needs to use complicated optimization and approximation methods to solve for the model parameters.

There is a trade-off between feature extraction and decision making. If the feature extractor is good, the task of the classifier (or regressor) becomes trivial, for example, when the class code is extracted as a new feature from the existing features. On the other hand, if the classifier is good enough, then there is no need for feature extraction; it does its automatic feature selection or combination internally. We live between these two ideal worlds.

There exist algorithms that do some feature selection internally, though in a limited way. Decision trees (chapter 9) do feature selection while generating the decision tree, and multilayer perceptrons (chapter 11) do nonlinear feature extraction in the hidden nodes. We expect to see more development along this line in coupling feature extraction and the later step of classification/regression.

6.8 Exercises

1. Assuming that the classes are normally distributed, in subset selection, when one variable is added or removed, how can the new discriminant be calculated quickly? For example, how can the new $\mathbf{S}_{new}^{-1}$ be calculated from $\mathbf{S}_{old}^{-1}$?
2. Using Optdigits from the UCI repository, implement PCA. For various number of eigenvectors, reconstruct the digit images and calculate the reconstruction error (equation 6.12).
3. Plot the map of your state/country using MDS, given the road travel distances as input.
4. In Sammon mapping, if the mapping is linear, namely, $g(\mathbf{x}|\mathbf{W}) = \mathbf{W}^T\mathbf{x}$, how can $\mathbf{W}$ that minimizes the Sammon stress be calculated?

7 Clustering

In the parametric approach, we assumed that the sample comes from a known distribution. In cases when such an assumption is untenable, we relax this assumption and use a semiparametric approach which allows a mixture of distributions to be used for estimating the input sample. Clustering methods allow learning the mixture parameters from data. In addition to probabilistic modeling, we discuss vector quantization and hierarchical clustering.

7.1 Introduction

IN CHAPTERS 4 and 5, we discussed the parametric method for density estimation where we assumed that the sample $\mathcal{X}$ is drawn from some parametric family, for example, Gaussian. In parametric classification, this corresponds to assuming a certain density for the class densities $p(\mathbf{x}|C_i)$. The advantage of any parametric approach is that given a model, the problem reduces to the estimation of a small number of parameters, which, in the case of density estimation, are the sufficient statistics of the density, for example, the mean and covariance in the case of Gaussian densities.

Though parametric approaches are used quite frequently, assuming a rigid parametric model may be a source of bias in many applications where this assumption does not hold. We thus need more flexible models. In particular, assuming Gaussian density corresponds to assuming that the sample, for example, instances of a class, forms one single group in the d-dimensional space, and as we saw in chapter 5, the center and the shape of this group is given by the mean and the covariance respectively.

In many applications, however, the sample is not one group; there may

be several groups. Consider the case of optical character recognition: There are two ways of writing the digit 7; the American writing is '7', whereas the European writing style has a horizontal bar in the middle (to tell it apart from the European '1' which keeps the small stroke on top in handwriting). In such a case, when the sample contains examples from both continents, the class for the digit 7 should be represented as the disjunction of two groups. If each of these groups can be represented by a Gaussian, the class can be represented by a *mixture* of two Gaussians, one for each writing style.

A similar example is in speech recognition where the same word can be uttered in different ways, due to different pronounciation, accent, gender, age, and so forth. Thus when there is not a single, universal prototype, all these different ways should be represented in the density to be statistically correct.

SEMIPARAMETRIC DENSITY ESTIMATION

We call this approach *semiparametric density estimation,* as we still assume a parametric model for each group in the sample. We discuss the *nonparametric* approach in chapter 8, which is used when there is no structure to the data and even a mixture model is not applicable. In this chapter, we focus on density estimation and defer supervised learning to chapter 12.

7.2 Mixture Densities

MIXTURE DENSITY

The *mixture density* is written as

$$p(\mathbf{x}) = \sum_{i=1}^{k} p(\mathbf{x}|\mathcal{G}_i) P(\mathcal{G}_i) \tag{7.1}$$

MIXTURE COMPONENTS
GROUPS
CLUSTERS
COMPONENT DENSITIES
MIXTURE PROPORTIONS

where $\mathcal{G}_i$ are the *mixture components.* They are also called *group* or *clusters.* $p(\mathbf{x}|\mathcal{G}_i)$ are the *component densities* and $P(\mathcal{G}_i)$ are the *mixture proportions.* k, the number of components, is a hyperparameter and should be specified beforehand. Given a sample and k, learning corresponds to estimating the component densities and proportions. When we assume that the component densities obey a parametric model, we need only estimate their parameters. If the component densities are multivariate Gaussian, we have $p(\mathbf{x}|\mathcal{G}_i) \sim \mathcal{N}(\boldsymbol{\mu}_i, \boldsymbol{\Sigma}_i)$, and $\Phi = \{P(\mathcal{G}_i), \boldsymbol{\mu}_i, \boldsymbol{\Sigma}_i\}_{i=1}^{k}$ are the parameters that should be estimated from the iid sample $\mathcal{X} = \{\mathbf{x}^t\}_t$.

Parametric classification is a bona fide mixture model where groups, $\mathcal{G}_i$, correspond to classes, C_i, component densities $p(\mathbf{x}|\mathcal{G}_i)$ correspond to class densities $p(\mathbf{x}|C_i)$ and $P(\mathcal{G}_i)$ correspond to class priors, $P(C_i)$:

$$p(\mathbf{x}) = \sum_{i=1}^{K} p(\mathbf{x}|C_i)P(C_i)$$

In this *supervised* case, we know how many groups there are and learning the parameters is trivial because we are given the labels, namely, which instance belongs to which class (component). We remember from chapter 5 that when we are given the sample $\mathcal{X} = \{\mathbf{x}^t, \mathbf{r}^t\}_{t=1}^N$, where $r_i^t = 1$ if $\mathbf{x}^t \in C_i$ and 0 otherwise, the parameters can be calculated using maximum likelihood. When each class is Gaussian distributed, we have a Gaussian mixture, and the parameters are estimated as

$$\begin{aligned} \hat{P}(C_i) &= \frac{\sum_t r_i^t}{N} \\ \mathbf{m}_i &= \frac{\sum_t r_i^t \mathbf{x}^t}{\sum_t r_i^t} \\ \mathbf{S}_i &= \frac{\sum_t r_i^t (\mathbf{x}^t - \mathbf{m}_i)(\mathbf{x}^t - \mathbf{m}_i)^T}{\sum_t r_i^t} \end{aligned} \tag{7.2}$$

The difference in this chapter is that the sample is $\mathcal{X} = \{\mathbf{x}^t\}_t$: We have an *unsupervised learning* problem. We are given only $\mathbf{x}^t$ and not the labels $\mathbf{r}^t$, that is, we do not know which $\mathbf{x}^t$ comes from which component. So we should estimate both: First, we should estimate the labels, r_i^t, the component that a given instance belongs to; and second, once we estimate the labels, we should estimate the parameters of the components given the set of instances belonging to them. We are first going to discuss a simple algorithm, k-means clustering, for this purpose and later on show that it is a special case of the *Expectation-Maximization* algorithm.

7.3 k-Means Clustering

Let us say we have an image that is stored with 24 bits/pixel and can have up to 16 million colors. Assume we have a color screen with 8 bits/pixel that can display only 256 colors. We want to find the best 256 colors among all 16 million colors such that the image using only the 256 colors in the palette looks as close as possible to the original image. This is *color quantization* where we map from high to lower resolution. In the general

COLOR QUANTIZATION

VECTOR QUANTIZATION

case, the aim is to map from a continuous space to a discrete space; this process is called *vector quantization.*

Of course we can always quantize uniformly but this wastes the colormap by assigning entries to colors not existing in the image, or would not assign extra entries to colors frequently used in the image. For example if the image is a seascape, we expect to see many shades of blue and maybe no red. So the distribution of the colormap entries should reflect the original density as close as possible placing many entries in high-density regions, discarding regions where there is no data.

REFERENCE VECTORS

Let us say we have a sample of $\mathcal{X} = \{\boldsymbol{x}^t\}_{t=1}^N$. We have k *reference vectors,* $\boldsymbol{m}_j, j = 1, \ldots, k$. In our example of color quantization, $\boldsymbol{x}^t$ are the image pixel values in 24 bits and $\boldsymbol{m}_j$ are the color map entries also in 24 bits, with $k = 256$.

Assume for now that we somehow have the $\boldsymbol{m}_j$ values; we will discuss how to learn them shortly. Then in displaying the image, given the pixel, $\boldsymbol{x}^t$, we represent it with the most similar entry, $\boldsymbol{m}_i$ in the color map, satisfying

$$\|\boldsymbol{x}^t - \boldsymbol{m}_i\| = \min_j \|\boldsymbol{x}^t - \boldsymbol{m}_j\|$$

CODEBOOK VECTORS
CODE WORDS

That is, instead of the original data value, we use the closest value we have in the alphabet of reference vectors. $\boldsymbol{m}_i$ are also called *codebook vectors* or *code words,* because this is a process of *encoding/decoding* (see figure 7.1): Going from $\boldsymbol{x}^t$ to i is a process of encoding the data using the codebook of $\boldsymbol{m}_i, i = 1, \ldots, k$ and on the receiving end, generating $\boldsymbol{m}_i$ from i is decoding.

COMPRESSION

Quantization also allows *compression:* For example, instead of using 24 bits to store (or transfer over a communication line) each $\boldsymbol{x}^t$, we can just store/transfer its index i in the colormap using 8 bits to index any one of 256, and we get a compression rate of almost 3; there is also the color map to store/transfer.

Let us see how we can calculate $\boldsymbol{m}_i$: When $\boldsymbol{x}^t$ is represented by $\boldsymbol{m}_i$, there is an error that is proportional to the distance, $\|\boldsymbol{x}^t - \boldsymbol{m}_i\|$. For the new image to look like the original image, we should have these distances as small as possible for all pixels. The total *reconstruction error* is defined as

RECONSTRUCTION ERROR

$$E(\{\boldsymbol{m}_i\}_{i=1}^k | \mathcal{X}) = \sum_t \sum_i b_i^t \|\boldsymbol{x}^t - \boldsymbol{m}_i\|^2 \tag{7.3}$$

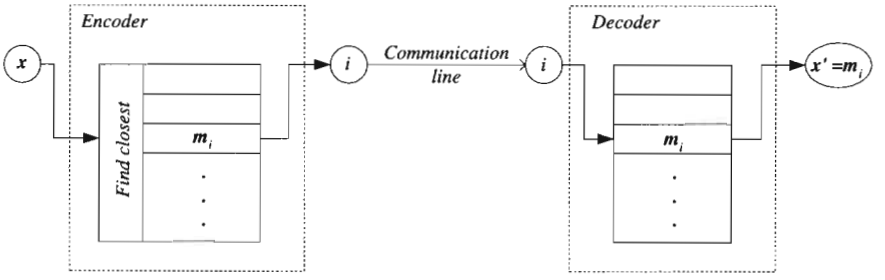

Figure 7.1 Given $\boldsymbol{x}$, the encoder sends the index of the closest code word and the decoder generates the code word with the received index as $\boldsymbol{x}'$. Error is $\|\boldsymbol{x}' - \boldsymbol{x}\|^2$.

where

$$b_i^t = \begin{cases} 1 & \text{if } \|\boldsymbol{x}^t - \boldsymbol{m}_i\| = \min_j \|\boldsymbol{x}^t - \boldsymbol{m}_j\| \\ 0 & \text{otherwise} \end{cases} \tag{7.4}$$

The best reference vectors are those that minimize the total reconstruction error. b_i^t also depend on $\boldsymbol{m}_i$ and we cannot solve this optimization problem analytically. We have an iterative procedure named *k-means clustering* for this: First, we start with some $\boldsymbol{m}_i$ initialized randomly. Then at each iteration, we first use equation 7.4 and calculate b_i^t for all $\boldsymbol{x}^t$, which are the *estimated labels;* if b_i^t is 1, we say that $\boldsymbol{x}^t$ belongs to the group of $\boldsymbol{m}_i$. Then, once we have these labels, we minimize equation 7.3. Taking its derivative with respect to $\boldsymbol{m}_i$ and setting it to 0, we get

k-MEANS CLUSTERING

$$\boldsymbol{m}_i = \frac{\sum_t b_i^t \boldsymbol{x}^t}{\sum_t b_i^t} \tag{7.5}$$

The reference vector is set to the mean of all the instances that it represents. Note that this is the same as the formula for the mean in equation 7.2, except that we place the estimated labels b_i^t in place of the labels r_i^t. This is an iterative procedure because once we calculate the new $\boldsymbol{m}_i$, b_i^t change and need to be recalculated which in turn affect $\boldsymbol{m}_i$. These two steps are repeated until $\boldsymbol{m}_i$ stabilize (see figure 7.2). The pseudocode of the k-means algorithm is given in figure 7.3.

One disadvantage is that this is a local search procedure and the final $\boldsymbol{m}_i$ highly depend on the initial $\boldsymbol{m}_i$. There are various methods for initialization:

- One can simply take randomly selected k instances as the initial $\boldsymbol{m}_i$.

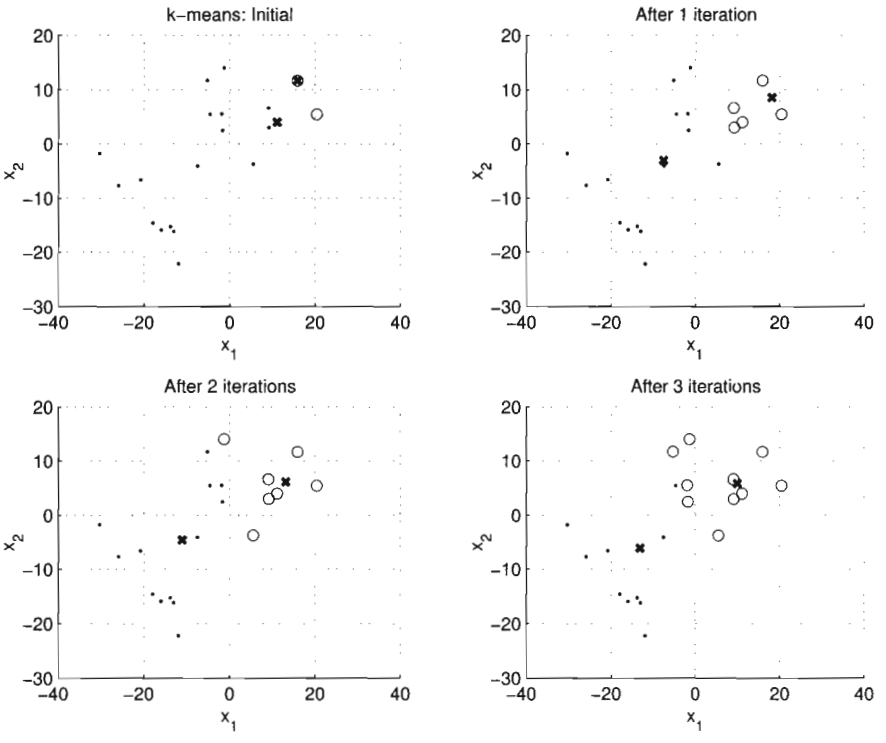

Figure 7.2 Evolution of k-means. Crosses indicate center positions. Data points are marked depending on the closest center.

- The mean of all data can be calculated and small random vectors may be added to the mean to get the k initial $\boldsymbol{m}_i$.
- One can calculate the principal component, divide its range into k equal intervals, partitioning the data into k groups, and then take the means of these groups as the initial centers.

After convergence, all the centers should cover some subset of the data instances and be useful, therefore it is best to initialize centers where we believe there is data.

LEADER CLUSTER ALGORITHM

There are also algorithms for adding new centers *incrementally* or deleting empty ones. In *leader cluster algorithm,* an instance that is far away from existing centers (defined by a threshold value) causes the creation of a new center at that point (We discuss such a neural network algorithm,

Initialize $\mathbf{m}_i, i = 1, \ldots, k$, for example, to k random $\mathbf{x}^t$
Repeat
  For all $\mathbf{x}^t \in \mathcal{X}$
    $$b_i^t \leftarrow \begin{cases} 1 & \text{if } \|\mathbf{x}^t - \mathbf{m}_i\| = \min_j \|\mathbf{x}^t - \mathbf{m}_j\| \\ 0 & \text{otherwise} \end{cases}$$
  For all $\mathbf{m}_i, i = 1, \ldots, k$
    $\mathbf{m}_i \leftarrow \sum_t b_i^t \mathbf{x}^t / \sum_t b_i^t$
Until $\mathbf{m}_i$ converge

Figure 7.3 k-means algorithm.

ART, in chapter 12). Or, a center that covers a large number of instances ($\sum_t b_i^t / N > \theta$) can be split into two (by adding a small random vector to one of the two copies to make them different). Similarly, a center that covers too few instances can be removed and restarted from some other part of the input space.

k-means algorithm is for clustering, that is, for finding groups in the data, where the groups are represented by their centers, which are the typical representatives of the groups. Vector quantization is one application of clustering, but clustering is also used for *preprocessing* before a later stage of classification or regression. Given $\mathbf{x}^t$, when we calculate b_i^t, we do a mapping from the original space to the k-dimensional space, that is, to one of the corners of the k-dimensional hypercube. A regression or discriminant function can then be learned in this new space; we discuss such methods in chapter 12.

7.4 Expectation-Maximization Algorithm

In k-means, we approached clustering as the problem of finding codebook vectors that minimize the total reconstruction error. In this section, our approach is probabilistic and we look for the component density parameters that maximize the likelihood of the sample. Using the mixture model of equation 7.1, the log likelihood of sample $\mathcal{X} = \{\mathbf{x}^t\}_t$ is

$$\begin{aligned} \mathcal{L}(\Phi|\mathcal{X}) &= \log \prod_t p(\mathbf{x}^t|\Phi) \\ &= \sum_t \log \sum_{i=1}^k p(\mathbf{x}^t|\mathcal{G}_i) P(\mathcal{G}_i) \end{aligned} \tag{7.6}$$

where Φ includes the priors $P(\mathcal{G}_i)$ and also the sufficient statistics of the component densities $p(\boldsymbol{x}^t|\mathcal{G}_i)$. Unfortunately, we cannot solve for the parameters analytically and need to resort to iterative optimization.

EXPECTATION-MAXIMIZATION

The *Expectation-Maximization* (EM) algorithm (Dempster, Laird, and Rubin 1977; Redner and Walker 1984) is used in maximum likelihood estimation where the problem involves two sets of random variables of which one, X, is observable and the other, Z, is hidden. The goal of the algorithm is to find the parameter vector Φ that maximizes the likelihood of the observed values of X, $\mathcal{L}(\Phi|\mathcal{X})$. But in cases where this is not feasible, we associate the extra *hidden variables* Z and express the underlying model using both, to maximize the likelihood of the joint distribution of X and Z, the *complete* likelihood $\mathcal{L}_c(\Phi|\mathcal{X},\mathcal{Z})$.

Since the Z values are not observed, we cannot work directly with the complete data likelihood $\mathcal{L}_c$, instead we work with its expectation, $\mathcal{Q}$, given $\mathcal{X}$ and the current parameter values Φ^l, where l indexes iteration. This is the *expectation* (E) step of the algorithm. Then in the *maximization* (M) step, we look for the new parameter values, Φ^{l+1}, that maximize this. Thus

$$\begin{aligned}\text{E-step} &: \mathcal{Q}(\Phi|\Phi^l) = E[\mathcal{L}_c(\Phi|\mathcal{X},\mathcal{Z})|\mathcal{X},\Phi^l]\\ \text{M-step} &: \Phi^{l+1} = \arg\max_{\Phi} \mathcal{Q}(\Phi|\Phi^l)\end{aligned}$$

Dempster, Laird, and Rubin (1977) proved that an increase in $\mathcal{Q}$ implies an increase in the incomplete likelihood

$$\mathcal{L}(\Phi^{l+1}|\mathcal{X}) \geq \mathcal{L}(\Phi^l|\mathcal{X})$$

In the case of mixtures, the hidden variables are the sources of observations, namely, which observation belongs to which component. If these were given, for example, as class labels in a supervised setting, we would know which parameters to adjust to fit that data point. The EM algorithm works as follows: In the E-step we estimate these labels given our current knowledge of components, and in the M-step we update our class knowledge given the labels estimated in the E-step. These two steps are the same as the two steps of k-means; calculation of b_i^t (E-step) and reestimation of $\boldsymbol{m}_i$ (M-step).

We define a vector of *indicator variables* $\boldsymbol{z}^t = \{z_1^t, \ldots, z_k^t\}$ where $z_i^t = 1$ if $\boldsymbol{x}^t$ belongs to cluster $\mathcal{G}_i$, and 0 otherwise. $\boldsymbol{z}$ is a multinomial distribu-

tion from k categories with prior probabilities π_i, shorthand for $P(\mathcal{G}_i)$. Then

$$P(\mathbf{z}^t) = \prod_{i=1}^{k} \pi_i^{z_i^t} \tag{7.7}$$

The likelihood of an observation $\mathbf{x}^t$ is equal to its probability specified by the component that generated it:

$$p(\mathbf{x}^t|\mathbf{z}^t) = \prod_{i=1}^{k} p_i(\mathbf{x}^t)^{z_i^t} \tag{7.8}$$

$p_i(\mathbf{x}^t)$ is shorthand for $p(\mathbf{x}^t|\mathcal{G}_i)$. The joint density is

$$p(\mathbf{x}^t, \mathbf{z}^t) = P(\mathbf{z}^t)p(\mathbf{x}^t|\mathbf{z}^t)$$

and the complete data likelihood of the iid sample $\mathcal{X}$ is

$$\begin{aligned}
\mathcal{L}_c(\Phi|\mathcal{X}, \mathcal{Z}) &= \log \prod_t p(\mathbf{x}^t, \mathbf{z}^t|\Phi) \\
&= \sum_t \log p(\mathbf{x}^t, \mathbf{z}^t|\Phi) \\
&= \sum_t \log P(\mathbf{z}^t|\Phi) + \log p(\mathbf{x}^t|\mathbf{z}^t, \Phi) \\
&= \sum_t \sum_i z_i^t [\log \pi_i + \log p_i(\mathbf{x}^t|\Phi)]
\end{aligned}$$

E-step: We define

$$\begin{aligned}
\mathcal{Q}(\Phi|\Phi^l) &\equiv E\left[\log P(X, Z)|\mathcal{X}, \Phi^l\right] \\
&= E\left[\mathcal{L}_c(\Phi|\mathcal{X}, \mathcal{Z})|\mathcal{X}, \Phi^l)\right] \\
&= \sum_t \sum_i E[z_i^t|\mathcal{X}, \Phi^l][\log \pi_i + \log p_i(\mathbf{x}^t|\Phi^l)]
\end{aligned}$$

where

$$\begin{aligned}
E[z_i^t|\mathcal{X}, \Phi^l] &= E[z_i^t|\mathbf{x}^t, \Phi^l] \quad \mathbf{x}^t \text{ are iid} \\
&= P(z_i^t = 1|\mathbf{x}^t, \Phi^l) \quad z_i^t \text{ is a 0/1 random variable} \\
&= \frac{p(\mathbf{x}^t|z_i^t = 1, \Phi^l)P(z_i^t = 1|\Phi^l)}{p(\mathbf{x}^t|\Phi^l)} \quad \text{Bayes' rule} \\
&= \frac{p_i(\mathbf{x}^t|\Phi^l)\pi_i}{\sum_j p_j(\mathbf{x}^t|\Phi^l)\pi_j}
\end{aligned}$$

$$= \frac{p(\mathbf{x}^t|\mathcal{G}_i,\Phi^l)P(\mathcal{G}_i)}{\sum_j p(\mathbf{x}^t|\mathcal{G}_j,\Phi^l)P(\mathcal{G}_j)}$$

$$= P(\mathcal{G}_i|\mathbf{x}^t,\Phi^l) \equiv h_i^t \tag{7.9}$$

We see that the expected value of the hidden variable, $E[z_i^t]$, is the posterior probability that $\mathbf{x}^t$ is generated by component $\mathcal{G}_i$. Because this is a probability, it is between 0 and 1 and is a "soft" label, as opposed to the 0/1 "hard" label of k-means.

M-step: We maximize $\mathcal{Q}$ to get the next set of parameter values Φ^{l+1}:

$$\Phi^{l+1} = \arg\max_{\Phi} \mathcal{Q}(\Phi|\Phi^l)$$

which is

$$\mathcal{Q}(\Phi|\Phi^l) = \sum_t \sum_i h_i^t [\log \pi_i + \log p_i(\mathbf{x}^t|\Phi^l)]$$

$$= \sum_t \sum_i h_i^t \log \pi_i + \sum_t \sum_i h_i^t \log p_i(\mathbf{x}^t|\Phi^l) \tag{7.10}$$

The second term is independent of π_i and using the constraint that $\sum_i \pi_i = 1$ as the Lagrangian, we solve for

$$\nabla_{\pi_i} \sum_t \sum_i h_i^t \log \pi_i - \lambda \left(\sum_i \pi_i - 1 \right) = 0$$

and get

$$\pi_i = \frac{\sum_t h_i^t}{N} \tag{7.11}$$

which is analogous to the calculation of priors in equation 7.2.

Similarly, the first term of equation 7.10 is independent of the components and can be dropped while estimating the parameters of the components. We solve for

$$\nabla_{\Phi} \sum_t \sum_i h_i^t \log p_i(\mathbf{x}^t|\Phi) = 0 \tag{7.12}$$

If we assume Gaussian components, $\hat{p}_i(\mathbf{x}^t|\Phi) \sim \mathcal{N}(\mathbf{m}_i, \mathbf{S}_i)$, the M-step is

$$\mathbf{m}_i^{l+1} = \frac{\sum_t h_i^t \mathbf{x}^t}{\sum_t h_i^t} \tag{7.13}$$

$$\mathbf{S}_i^{l+1} = \frac{\sum_t h_i^t (\mathbf{x}^t - \mathbf{m}_i^{l+1})(\mathbf{x}^t - \mathbf{m}_i^{l+1})^T}{\sum_t h_i^t}$$

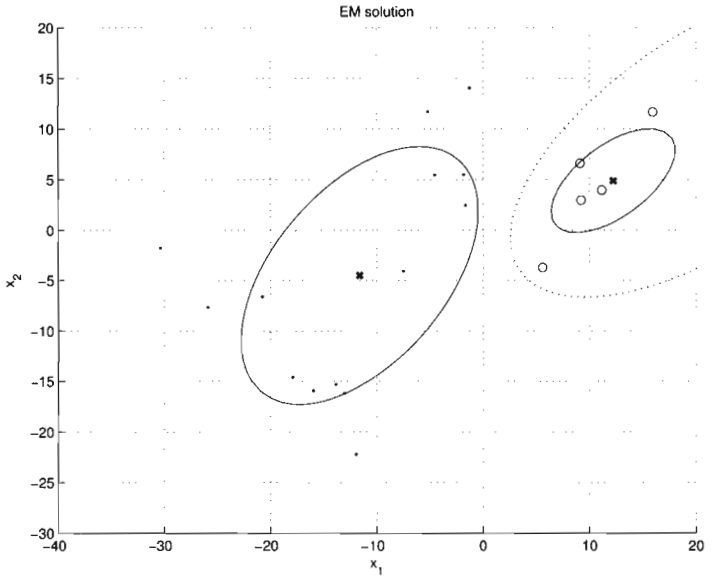

Figure 7.4 Data points and the fitted Gaussians by EM, initialized by one k-means iteration of figure 7.2. Unlike in k-means, as can be seen, EM allows estimating the covariance matrices. The data points labeled by greater h_i, the contours of the estimated Gaussian densities, and the separating curve of $h_i = 0.5$ (dashed line) are shown.

where, for Gaussian components in the E-step, we calculate

$$h_i^t = \frac{\pi_i |\mathbf{S}_i|^{-1/2} \exp[-(1/2)(\boldsymbol{x}^t - \boldsymbol{m}_i)^T \mathbf{S}_i^{-1} (\boldsymbol{x}^t - \boldsymbol{m}_i)]}{\sum_j \pi_j |\mathbf{S}_j|^{-1/2} \exp[-(1/2)(\boldsymbol{x}^t - \boldsymbol{m}_j)^T \mathbf{S}_j^{-1} (\boldsymbol{x}^t - \boldsymbol{m}_j)]} \tag{7.14}$$

Again, the similarity between equations 7.13 and 7.2 is not accidental; the estimated soft labels h_i^t replace the actual (unknown) labels r_i^t.

EM is initalized by k-means. After a few iterations of k-means, we get the estimates for the centers $\boldsymbol{m}_i$ and using the instances covered by each center, we estimate the $\mathbf{S}_i$ and $\sum_t b_i^t / N$ give us the π_i. We run EM from that point on, as shown in figure 7.4.

Just as in parametric classification (section 5.5), with small samples and large dimensionality we can regularize by making simplifying assumptions. When $\hat{p}_i(\boldsymbol{x}^t|\Phi) \sim \mathcal{N}(\boldsymbol{m}_i, \mathbf{S})$, the case of a shared covariance matrix,

equation 7.12 reduces to

$$\min_{\mathbf{m}_i,\mathbf{S}} \sum_t \sum_i h_i^t (\mathbf{x}^t - \mathbf{m}_i)^T \mathbf{S}^{-1} (\mathbf{x}^t - \mathbf{m}_i) \tag{7.15}$$

When $\hat{p}_i(\mathbf{x}^t|\Phi) \sim \mathcal{N}(\mathbf{m}_i, s^2\mathbf{I})$, the case of a shared diagonal matrix, we have

$$\min_{\mathbf{m}_i,s} \sum_t \sum_i h_i^t \frac{\|\mathbf{x}^t - \mathbf{m}_i\|^2}{s^2} \tag{7.16}$$

which is the reconstruction error we defined in k-means clustering (equation 7.3). The difference is that now

$$h_i^t = \frac{\exp\left[-(1/2s^2)\|\mathbf{x}^t - \mathbf{m}_i\|^2\right]}{\sum_j \exp\left[-(1/2s^2)\|\mathbf{x}^t - \mathbf{m}_j\|^2\right]} \tag{7.17}$$

is a probability between 0 and 1. b_i^t of k-means clustering makes a hard 0/1 decision, whereas h_i^t is a *soft label* that assigns the input to a cluster with a certain probability. When h_i^t are used instead of b_i^t, an instance contributes to the update of parameters of all components, to each with a certain probability. This is especially useful if the instance is close to the midpoint between two centers. We thus see that k-means clustering is a special case of EM applied to Gaussian mixtures where inputs are assumed independent with equal and shared variances and where labels are hardened. k-means thus pave the input density with circles, whereas EM in the general case uses ellipses of arbitrary shapes and orientations.

7.5 Mixtures of Latent Variable Models

When full covariance matrices are used with Gaussian mixtures, even if there is no singularity, one risks overfitting if the input dimensionality is high and the sample is small. To decrease the number of parameters, assuming a common covariance matrix may not be right since clusters may really have different shapes. Assuming diagonal matrices is even more risky because it removes all correlations. The alternative is to do dimensionality reduction in the clusters. This decreases the number of parameters while still capturing the correlations. The number of free parameters is controlled through the dimensionality of the reduced space.

When we do factor analysis in the clusters, we look for *latent* or *hidden variables* or *factors* that generate the data in the clusters (Bishop 1999):

$$p(\mathbf{x}^t|\mathcal{G}_i) \sim \mathcal{N}(\mathbf{m}_i, \mathbf{V}_i\mathbf{V}_i^T + \mathbf{\Psi}_i) \tag{7.18}$$

where $\mathbf{V}_i$ and $\mathbf{\Psi}_i$ are the factor loadings and specific variances of cluster $\mathcal{G}_i$. Rubin and Thayer (1982) give EM equations for factor analysis. It is possible to extend this in mixture models to find *mixtures of factor analyzers* (Ghahramani and Hinton 1997). Similarly, one can also do PCA in groups, which is called *mixtures of probabilistic principal component analyzers* (Tipping and Bishop 1999).

MIXTURES OF FACTOR ANALYZERS

MIXTURES OF PROBABILISTIC PRINCIPAL COMPONENT ANALYZERS

We can of course use EM to learn $\mathbf{S}_i$ and then do FA or PCA separately in each cluster, but doing EM is better because it couples these two steps and does a soft partitioning. An instance contributes to the calculation of the latent variables of all groups, weighted by h_i^t.

7.6 Supervised Learning after Clustering

Clustering, like the dimensionality reduction methods discussed in chapter 6, can be used for two purposes: It can be used for data exploration, to understand the structure of data. Dimensionality reduction methods are used to find correlations between variables and thus group variables. Clustering methods are used to find similarities between instances and thus group instances.

If such groups are found, these may be named (by application experts) and their attributes be defined. One can choose the group mean as the representative prototype of instances in the group, or the possible range of attributes can be written. This allows a simpler description of the data. For example, if the customers of a company seem to fall in one of k groups, customers being defined in terms of their demographic attributes and transactions with the company, then a better understanding of the customer base will be provided which will allow the company to provide different strategies for different types of customers. Likewise, the company will also be able to develop strategies for those customers who do not fall in any large group, and who may require attention, for example, churning customers.

Frequently, clustering is also used as a preprocessing stage. Just like the dimensionality reduction methods of chapter 6 allowed us to make a mapping to a new space, after clustering, we also map to a new k-dimensional space where the dimensions are h_i (or b_i at the risk of loss of information). In a supervised setting, we can then learn the discriminant or regression function in this new space. The difference from dimension-

ality reduction methods like PCA however is that k, the dimensionality of the new space, can be larger than d, the original dimensionality.

When we use a method like PCA, where the new dimensions are combinations of the original dimensions, to represent any instance in the new space, all dimensions contribute, that is, all z_j are nonzero. In the case of a method like clustering where the new dimensions are defined locally, there are many more new dimensions, b_j, but only one (or if we use h_j, few) of them have a nonzero value. In the former case, there are few dimensions but all contribute to the representation; in the latter case, there are many dimensions but few contribute.

One advantage of preceding a supervised learner with unsupervised clustering or dimensionality reduction is that the latter does not need labeled data. Labeling the data is costly. We can use a large amount of unlabeled data for learning the cluster parameters and then use a smaller labeled data to learn the second stage of classification or regression. Unsupervised learning is called "learning what normally happens" (Barrow 1989). When followed by a supervised learner, we first learn what normally happens and then learn what that means. We discuss such methods in chapter 12.

MIXTURE OF MIXTURES

In the case of classification, when each class is a mixture model composed of a number of components, the whole density is a *mixture of mixtures:*

$$p(\mathbf{x}|C_i) = \sum_{j=1}^{k_i} p(\mathbf{x}|\mathcal{G}_{ij})P(\mathcal{G}_{ij})$$

$$p(\mathbf{x}) = \sum_{i=1}^{K} p(\mathbf{x}|C_i)P(C_i)$$

where k_i is the number of components making up $p(\mathbf{x}|C_i)$ and $\mathcal{G}_{ij}$ is the component j of class i. Learning the parameters of components is done separately for each class (probably after some regularization) as we discussed previously. This is better than fitting many components to data from all classes and then labeling them later with classes.

7.7 Hierarchical Clustering

We discussed clustering from a probabilistic point of view as fitting a mixture model to the data, or in terms of finding code words minimizing

reconstruction error. There are also methods for clustering that only use similarities of instances, without any other requirement on the data; the aim is to find groups such that instances in a group are more similar to each other than instances in different groups. This is the approach taken by *hierarchical clustering.*

HIERARCHICAL CLUSTERING

This needs the use of a similarity, or equivalently a distance, measure defined between instances. Generally Euclidean distance is used, where one needs to make sure that all attributes have the same scale. This is a special case of the *Minkowksi distance* with $p = 2$:

$$d_m(\mathbf{x}^r, \mathbf{x}^s) = \left[\sum_{j=1}^{d} (x_j^r - x_j^s)^p\right]^{1/p}$$

City-block distance is easier to calculate:

$$d_{cb}(\mathbf{x}^r, \mathbf{x}^s) = \sum_{j=1}^{d} |x_j^r - x_j^s|$$

AGGLOMERATIVE CLUSTERING

DIVISIVE CLUSTERING

An *agglomerative clustering* algorithm starts with N groups, each initially containing one training instance, merging similar groups to form larger groups, until there is a single one. A *divisive clustering* algorithm goes in the other direction, starting with a single group and dividing large groups into smaller groups, until each group contains a single instance.

SINGLE-LINK CLUSTERING

At each iteration of an agglomerative algorithm, we choose the two closest groups to merge. In *single-link clustering,* this distance is defined as the smallest distance between all possible pair of elements of the two groups:

$$d(\mathcal{G}_i, \mathcal{G}_j) = \min_{\mathbf{x}^r \in \mathcal{G}_i, \mathbf{x}^s \in \mathcal{G}_j} d(\mathbf{x}^r, \mathbf{x}^s) \tag{7.19}$$

Consider a weighted, completely connected graph with nodes corresponding to instances and edges between nodes with weights equal to the distances between the instances. Then the single-link method corresponds to constructing the minimal spanning tree of this graph.

COMPLETE-LINK CLUSTERING

In *complete-link clustering,* the distance between two groups is taken as the largest distance between all possible pairs:

$$d(\mathcal{G}_i, \mathcal{G}_j) = \max_{\mathbf{x}^r \in \mathcal{G}_i, \mathbf{x}^s \in \mathcal{G}_j} d(\mathbf{x}^r, \mathbf{x}^s) \tag{7.20}$$

These are the two most frequently used measures to choose the two closest groups to merge. Other possibilities are the average-link method

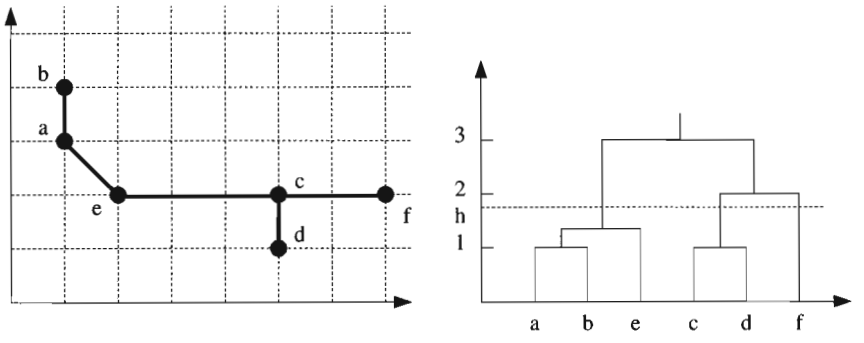

Figure 7.5 A two-dimensional dataset and the dendrogram showing the result of single-link clustering is shown. Note that leaves of the tree are ordered so that no branches cross. The tree is then intersected at a desired value of h to get the clusters.

that uses the average of distances between all pairs and the centroid distance that measures the distance between the centroids (means) of the two groups.

DENDROGRAM

Once an agglomerative method is run, the result is generally drawn as a hierarchical structure known as the *dendrogram*. This is a tree where leaves correspond to instances, which are grouped in the order they are merged. An example is given in figure 7.5. The tree can be then intersected at any level to get the wanted number of groups.

Single-link and complete-link methods calculate the distance between groups differently that affect the clusters and the dendrogram: In the single-link method, two instances are grouped together at level h if the distance between them is less than h, or if there is an intermediate sequence of instances between them such that the distance between consecutive instances is less than h. On the other hand, in the complete-link method, all instances in a group have a distance less than h between them. Single-link clusters may be elongated due to this "chaining" effect. (In figure 7.5, what if there were an instance halfway between e and c?) Complete-link clusters tend to be more compact.

7.8 Choosing the Number of Clusters

Like any learning method, clustering also has its knob to adjust complexity; it is k, the number of clusters. Given any k, clustering will always find k centers, whether they really are meaningful groups, or whether they are imposed by the method we use. There are various ways we can use to fine-tune k:

- In some applications such as color quantization, k is defined by the application.
- Plotting the data in two dimensions using PCA may be used in uncovering the structure of data and the number of clusters in the data.
- An incremental approach may also help: Setting a maximum allowed distance is equivalent to setting a maximum allowed reconstruction error per instance.
- In some applications, validation of the groups can be done manually by checking whether clusters actually code meaningful groups of the data. For example, in a data mining application, application experts may do this check. In color quantization, we may inspect the image visually to check its quality (despite the fact that our eyes and brain do not analyze an image pixel by pixel).

Depending on what type of clustering method we use, we can plot the reconstruction error or log likelihood as a function of k, and look for the "elbow." After a large enough k, the algorithm will start dividing groups, in which case there will not be a large decrease in the reconstruction error or large increase in the log likelihood. Similarly in hierarchical clustering, by looking at the differences between levels in the tree, we can decide on a good split.

7.9 Notes

Mixture models are frequently used in statistics. Dedicated textbooks are those by Titterington, Smith, and Makov (1985) and McLachlan and Basford (1988). McLachlan and Krishnan (1997) discuss recent developments in EM algorithm, how its convergence can be accelerated, and various variants. In signal processing, k-means is called the *Linde-Buzo-Gray* (LBG) algorithm (Gersho and Gray 1992). It is frequently used in both statistics

FUZZY k-MEANS

and signal processing in a large variety of applications and has many variants, one of which is *fuzzy k-means.* The *fuzzy membership* of an input to a component is also a number between 0 and 1 (Bezdek and Pal 1995). Alpaydın (1998) compares k-means, fuzzy k-means, and EM on Gaussian mixtures. A comparison of EM and other learning algorithms for the learning of Gaussian mixture models is given by Xu and Jordan (1996). On small data samples, an alternative to simplifying assumptions is to use a Bayesian approach (Ormoneit and Tresp 1996). Moerland (1999) compares mixtures of Gaussians and mixtures of latent variable models on a set of classification problems, showing the advantage of latent variable models empirically. A book on clustering methods is by Jain and Dubes (1988) and a survey article is by Jain, Murty, and Flynn (1999).

7.10 Exercises

1. In image compression, k-means can be used as follows: The image is divided into nonoverlapping $c \times c$ windows and these c^2-dimensional vectors make up the sample. For a given k, which is generally a power of two, we do k-means clustering. The reference vectors and the indices for each window is sent over the communication line. At the receiving end, the image is then reconstructed by reading from the table of reference vectors using the indices. Write the computer program that does this for different values of k and c. For each case, calculate the reconstruction error and the compression rate.
2. We can do k-means clustering, partition the instances, and then calculate $\mathbf{S}_i$ separately in each group. Why is this not a good idea?
3. Derive the M-step equations for $\mathbf{S}$ in the case of shared arbitrary covariance matrix $\mathbf{S}$ (equation 7.15) and s^2, in the case of shared diagonal covariance matrix (equation 7.16).
4. Define a multivariate Bernoulli mixture where inputs are binary and derive the EM equations.

8 Nonparametric Methods

In the previous chapters, we discussed the parametric and semiparametric approaches where we assumed that the data is drawn from one or a mixture of probability distributions of known form. Now, we are going to discuss the nonparametric approach that is used when no such assumption can be made on the input density and the data speaks for itself. We consider the nonparametric approaches for density estimation, classification, and regression and see how the time and space complexity can be checked.

8.1 Introduction

IN PARAMETRIC methods, whether for density estimation, classification, or regression, we assume a model valid over the whole input space. In regression, for example, when we assume a linear model, we assume that for any input, the output is the same linear function of the input. In classification when we assume a normal density, we assume that all examples of the class are drawn from this same density. The advantage of a parametric method is that it reduces the problem of estimating a probability density function, discriminant, or regression function to estimating the values of a small number of parameters. Its disadvantage is that this assumption does not always hold and we may incur a large error if it does not.

If we cannot make such assumptions and cannot come up with a parametric model, one possibility is to use a semiparametric mixture model as we saw in chapter 7 where the density is written as a disjunction of a small number of parametric models. In *nonparametric estimation,* all we assume is that *similar inputs have similar outputs.* This is a reason-

NONPARAMETRIC ESTIMATION

able assumption: The world is smooth and functions, whether they are densities, discriminants, or regression functions, change slowly. Similar instances mean similar things. We all love our neighbors because they are so much like us.

Therefore, our algorithm is composed of finding the similar past instances from the training set using a suitable distance measure and interpolating from them to find the right output. Different nonparametric methods differ in the way they define similarity or interpolate from the similar training instances. In a parametric model, all of the training instances affect the final global estimate, whereas in the nonparametric case, there is no single global model; local models are estimated as they are needed, affected only by the training instances closeby.

INSTANCE-BASED
MEMORY-BASED
LEARNING

In machine learning literature, nonparametric methods are also called *instance-based* or *memory-based learning* algorithms, since what they do is store the training instances in a lookup table and interpolate from these. This implies that all of the training instances should be stored and storing all requires memory of $\mathcal{O}(N)$. Furthermore, given an input, similar ones should be found, and finding them requires computation of $\mathcal{O}(N)$. Such methods are also called *lazy* learning algorithms, because unlike the *eager* parametric models, they do not compute a model when they are given the training set but postpone the computation of the model until they are given a test instance. In the case of a parametric approach, the model is quite simple and has a small number of parameters, of order $\mathcal{O}(d)$, or $\mathcal{O}(d^2)$, and once these parameters are calculated from the training set, we keep the model and no longer need the training set to calculate the output. N is generally much larger than d (or d^2), and this increased need for memory and computation is the disadvantage of the nonparametric methods.

We start by estimating a density function, and discuss its use in classification. We then generalize the approach to regression.

8.2 Nonparametric Density Estimation

As usual in density estimation, we assume that the sample $\mathcal{X} = \{x^t\}_{t=1}^N$ is drawn independently from some unknown probability density $p(\cdot)$. $\hat{p}(\cdot)$ is our estimator of $p(\cdot)$. We start with the univariate case where x^t are scalars and later generalize to the multidimensional case.

The nonparametric estimator for the cumulative distribution function,

$F(x)$, at point x is the proportion of sample points that are less than or equal to x

$$\hat{F}(x) = \frac{\#\{x^t \leq x\}}{N} \tag{8.1}$$

where $\#\{x^t \leq x\}$ denotes the number of training instances whose x^t is less than or equal to x. Similarly, the nonparametric estimate for the density function can be calculated as

$$\hat{p}(x) = \frac{1}{h}\left[\frac{\#\{x^t \leq x + h\} - \#\{x^t \leq x\}}{N}\right] \tag{8.2}$$

h is the length of the interval and instances x^t that fall in this interval are assumed to be "close enough." The techniques given in this chapter are variants where different heuristics are used to determine the instances that are close and their effects on the estimate.

8.2.1 Histogram Estimator

HISTOGRAM

The oldest and most popular method is the *histogram* where the input space is divided into equal sized intervals named *bins*. Given an origin x_o and a bin width h, the bins are the intervals $[x_o + mh, x_o + (m+1)h)$ for positive and negative integers m and the estimate is given as

$$\hat{p}(x) = \frac{\#\{x^t \text{ in the same bin as } x\}}{Nh} \tag{8.3}$$

In constructing the histogram, we have to choose both an origin and a bin width. The choice of origin affects the estimate near boundaries of bins, but it is mainly the bin width that has an effect on the estimate: With small bins, the estimate is spiky, and with larger bins, the estimate is smoother (see figure 8.1). The estimate is 0 if no instance falls in a bin and there are discontinuities at bin boundaries. Still, one advantage of the histogram is that once the bin estimates are calculated and stored, we do not need to retain the training set.

NAIVE ESTIMATOR

The *naive estimator* (Silverman 1986) frees us from setting an origin. It is defined as

$$\hat{p}(x) = \frac{\#\{x - h < x^t \leq x + h\}}{2Nh} \tag{8.4}$$

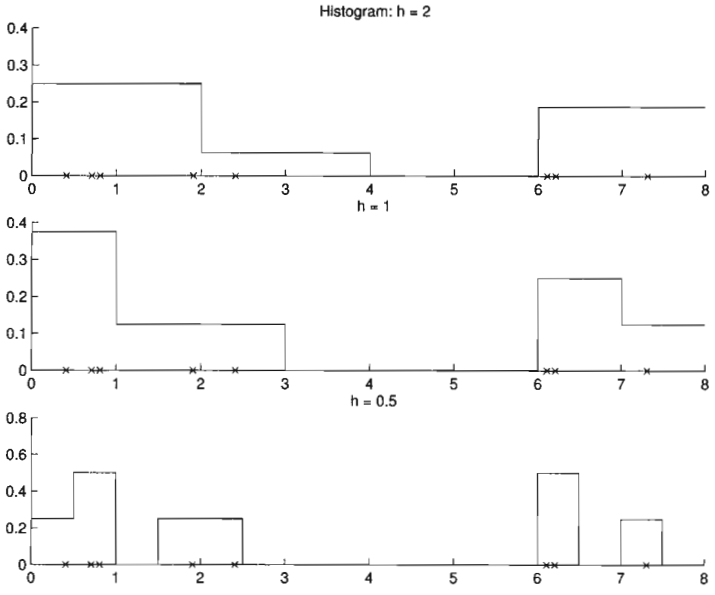

Figure 8.1 Histograms for various bin lengths. '×' denote data points.

and is equal to the histogram estimate where x is always at the center of a bin of size $2h$ (see figure 8.2). The estimator can also be written as

$$\hat{p}(x) = \frac{1}{Nh} \sum_{t=1}^{N} w\left(\frac{x - x^t}{h}\right) \tag{8.5}$$

with the *weight function* defined as

$$w(u) = \begin{cases} \frac{1}{2} & \text{if } |u| < 1 \\ 0 & \text{otherwise} \end{cases}$$

This is as if each x^t has a symmetric region of influence of size $2h$ around it and contributes $\frac{1}{2}$ for an x falling in its region. Then the nonparametric estimate is just the sum of influences of x^t whose regions include x. Because this region of influence is "hard" (0 or $\frac{1}{2}$), the estimate is not a continuous function and has jumps at $x^t \pm h$.

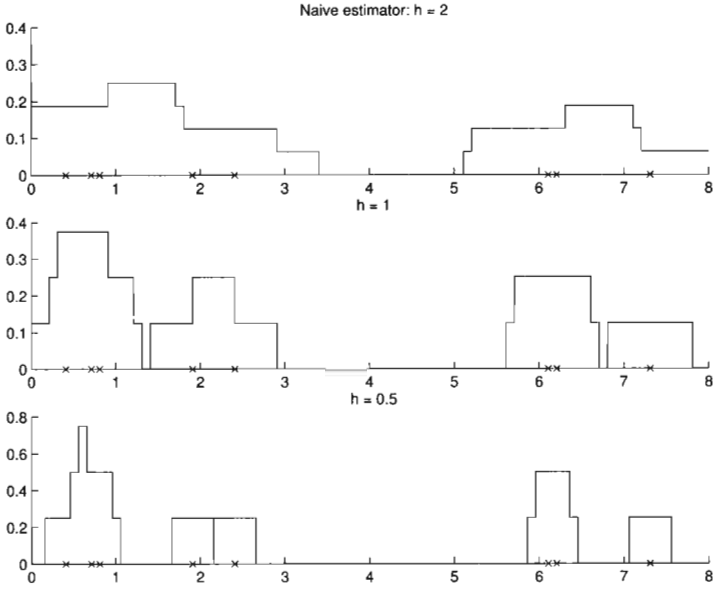

Figure 8.2 Naive estimate for various bin lengths.

8.2.2 Kernel Estimator

KERNEL FUNCTION

To get a smooth estimate, we use a smooth weight function, called a *kernel function.* The most popular is the Gaussian kernel:

$$K(u) = \frac{1}{\sqrt{2\pi}} \exp\left[-\frac{u^2}{2}\right] \tag{8.6}$$

KERNEL ESTIMATOR
PARZEN WINDOWS

The *kernel estimator,* also called *Parzen windows,* is defined as

$$\hat{p}(x) = \frac{1}{Nh} \sum_{t=1}^{N} K\left(\frac{x - x^t}{h}\right) \tag{8.7}$$

The kernel function $K(\cdot)$ determines the shape of the influences and the window width h determines the width. Just like the naive estimate is the sum of "boxes," the kernel estimate is the sum of "bumps." All the x^t have an effect on the estimate at x and this effect decreases smoothly as $|x - x^t|$ increases.

To simplify calculation, $K(\cdot)$ can be taken to be 0 if $|x - x^t| > 3h$. There exist other kernels easier to compute that can be used, as long as $K(u)$ is maximum for $u = 0$ and decreasing symmetrically as $|u|$ increases.

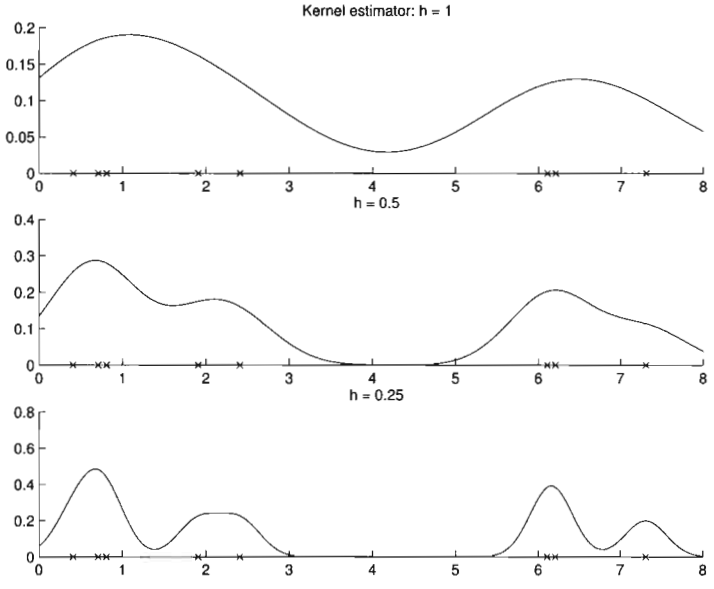

Figure 8.3 Kernel estimate for various bin lengths.

When h is small, each training instance has a large effect in a small region and no effect on distant points. When h is larger, there is more overlap of the kernels and we get a smoother estimate (see figure 8.3). If $K(\cdot)$ is everywhere nonnegative and integrates to 1, namely, if it is a legitimate density function, so will $\hat{p}(\cdot)$ be. Furthermore, $\hat{p}(\cdot)$ will inherit all the continuity and differentiability properties of the kernel $K(\cdot)$, so that, for example, if $K(\cdot)$ is Gaussian, then $\hat{p}(\cdot)$ will be smooth having all the derivatives.

One problem is that the window width is fixed across the entire input space. Various adaptive methods have been proposed to tailor h as a function of the density around x.

8.2.3 k-Nearest Neighbor Estimator

The nearest neighbor class of estimators adapts the amount of smoothing to the *local* density of data. The degree of smoothing is controlled by k, the number of neighbors taken into account, which is much smaller than

N, the sample size. Let us define a distance between a and b, for example, $|a - b|$, and for each x, we define

$$d_1(x) \leq d_2(x) \leq \cdots \leq d_N(x)$$

to be the distances arranged in ascending order, from x to the points in the sample: $d_1(x)$ is the distance to the nearest sample, $d_2(x)$ is the distance to the next nearest, and so on. If x^t are the data points, then we define $d_1(x) = \min_t |x - x^t|$ and if i is the index of the closest sample, namely, $i = \arg\min_t |x - x^t|$, then $d_2(x) = \min_{j \neq i} |x - x^j|$, and so forth.

k-NEAREST NEIGHBOR ESTIMATE

The *k-nearest neighbor* (k-nn) density estimate is

$$\hat{p}(x) = \frac{k}{2Nd_k(x)} \tag{8.8}$$

This is like a naive estimator with $h = d_k(x)$, the difference being that instead of fixing h and checking how many samples fall in the bin, we fix k, the number of observations to fall in the bin, and compute the bin size. Where density is high, bins are small, and where density is low, bins are larger (see figure 8.4).

The k-nn estimator is not continuous; its derivative has a discontinuity at all $\frac{1}{2}(x^{(j)} + x^{(j+k)})$ where $x^{(j)}$ are the order statistics of the sample. The k-nn is not a probability density function since it integrates to ∞, not 1.

To get a smoother estimate, we can use a kernel function whose effect decreases with increasing distance

$$\hat{p}(x) = \frac{1}{Nd_k(x)} \sum_{t=1}^{N} K\left(\frac{x - x^t}{d_k(x)}\right) \tag{8.9}$$

This is like a kernel estimator with adaptive smoothing parameter $h = d_k(x)$. $K(\cdot)$ is typically taken to be the Gaussian kernel.

8.3 Generalization to Multivariate Data

Given a sample of d-dimensional observations $\mathcal{X} = \{\boldsymbol{x}^t\}_{t=1}^N$, the multivariate kernel density estimator is

$$\hat{p}(\boldsymbol{x}) = \frac{1}{Nh^d} \sum_{t=1}^{N} K\left(\frac{\boldsymbol{x} - \boldsymbol{x}^t}{h}\right) \tag{8.10}$$

with the requirement that

$$\int_{\Re^d} K(\boldsymbol{x}) d\boldsymbol{x} = 1$$

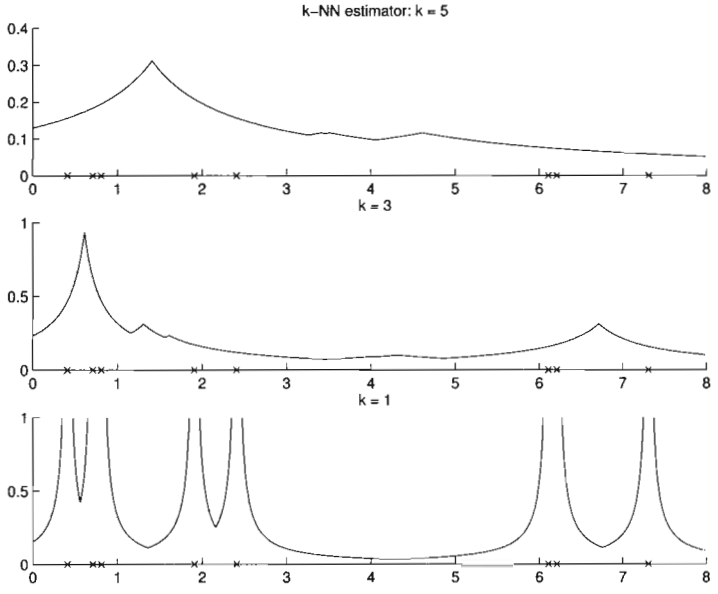

Figure 8.4 k-nearest neighbor estimate for various k values.

The obvious candidate is the multivariate Gaussian kernel:

$$K(\boldsymbol{u}) = \left(\frac{1}{\sqrt{2\pi}}\right)^d \exp\left[-\frac{\|\boldsymbol{u}\|^2}{2}\right] \tag{8.11}$$

CURSE OF DIMENSIONALITY

However, care should be applied to using nonparametric estimates in high-dimensional spaces because of the *curse of dimensionality:* Let us say $\boldsymbol{x}$ is eight-dimensional, and we use a histogram with ten bins per dimension, then there are 10^8 bins, and unless we have lots of data, most of these bins will be empty and the estimates in there will be 0. In high dimensions, the concept of "close" also becomes blurry so one should be careful in choosing h.

For example, the use of a single smoothing parameter h in equation 8.11 implies that the kernel is scaled equally on all dimensions. If the inputs are on different scales, they should be normalized to have the same variance. Still, this does not take correlations into account and better results are achieved when the kernel has the same form as the underlying distribution

$$K(\boldsymbol{u}) = \frac{1}{(2\pi)^{d/2}|\mathbf{S}|^{1/2}} \exp\left[-\frac{1}{2}\boldsymbol{u}^T\mathbf{S}^{-1}\boldsymbol{u}\right] \tag{8.12}$$

where $\mathbf{S}$ is the sample covariance matrix. This corresponds to using Mahalanobis distance instead of the Euclidean distance.

It is also possible to have the distance metric local where $\mathbf{S}$ is calculated from instances in the vicinity of $\mathbf{x}$, for example, some k closest instances. Note that $\mathbf{S}$ calculated locally may be singular and PCA (or LDA, in the case of classification) may be needed.

HAMMING DISTANCE When the inputs are discrete, we can use *Hamming distance*, which counts the number of nonmatching attributes

$$HD(\mathbf{x}, \mathbf{x}^t) = \sum_{j=1}^{d} 1(x_j \neq x_j^t) \tag{8.13}$$

where

$$1(x_j \neq x_j^t) = \begin{cases} 1 & \text{if } x_j \neq x_j^t \\ 0 & \text{otherwise} \end{cases}$$

$HD(\mathbf{x}, \mathbf{x}^t)$ is then used in place of $\|\mathbf{x} - \mathbf{x}^t\|$ or $(\mathbf{x} - \mathbf{x}^t)^T \mathbf{S}^{-1} (\mathbf{x} - \mathbf{x}^t)$ for kernel estimation or for finding the k closest neighbors.

8.4 Nonparametric Classification

When used for classification, we use the nonparametric approach to estimate the class-conditional densities, $p(\mathbf{x}|C_i)$. The kernel estimator of the class-conditional density is given as

$$\hat{p}(\mathbf{x}|C_i) = \frac{1}{N_i h^d} \sum_{t=1}^{N} K\left(\frac{\mathbf{x} - \mathbf{x}^t}{h}\right) r_i^t \tag{8.14}$$

where r_i^t is 1 if $\mathbf{x}^t \in C_i$ and 0 otherwise. N_i is the number of labeled instances belonging to C_i: $N_i = \sum_t r_i^t$. The MLE of the prior density is $\hat{P}(C_i) = N_i/N$. Then, the discriminant can be written as

$$\begin{aligned} g_i(\mathbf{x}) &= \hat{p}(\mathbf{x}|C_i)\hat{P}(C_i) \\ &= \frac{1}{N h^d} \sum_{t=1}^{N} K\left(\frac{\mathbf{x} - \mathbf{x}^t}{h}\right) r_i^t \end{aligned} \tag{8.15}$$

and $\mathbf{x}$ is assigned to the class for which the discriminant takes its maximum. The common factor $1/(Nh^d)$ can be ignored. So each training instance votes for its class and has no effect on other classes; the weight

of vote is given by the kernel function $K(\cdot)$, typically giving more weight to closer instances.

For the special case of k-nn estimator, we have

$$\hat{p}(\boldsymbol{x}|C_i) = \frac{k_i}{N_i V^k(\boldsymbol{x})} \tag{8.16}$$

where k_i is the number of neighbors out of the k nearest that belong to C_i and $V^k(\boldsymbol{x})$ is the volume of the d-dimensional hypersphere centered at $\boldsymbol{x}$, with radius $r = \|\boldsymbol{x} - \boldsymbol{x}_{(k)}\|$ where $\boldsymbol{x}_{(k)}$ is the k-th nearest observation to $\boldsymbol{x}$ (among all neighbors from all classes of $\boldsymbol{x}$): $V^k = r^d c_d$ with c_d as the volume of the unit sphere in d dimensions, for example, $c_1 = 2, c_2 = \pi, c_3 = 4\pi/3$, and so forth. Then

$$\hat{P}(C_i|\boldsymbol{x}) = \frac{\hat{p}(\boldsymbol{x}|C_i)\hat{P}(C_i)}{\hat{p}(\boldsymbol{x})} = \frac{k_i}{k} \tag{8.17}$$

k-NN CLASSIFIER

The *k-nn classifier* assigns the input to the class having most examples among the k neighbors of the input. All neighbors have equal vote, and the class having the maximum number of voters among the k neighbors is chosen. Ties are broken arbitrarily or a weighted vote is taken. k is generally taken an odd number to minimize ties: Confusion is generally between two neighboring classes.

Again, the use of Euclidean distance corresponds to assuming uncorrelated inputs with equal variances and when this is not the case, a suitable metric should be used. One example is *discriminant adaptive nearest neighbor* (Hastie and Tibshirani 1996) where the optimal distance to separate classes is estimated locally.

DISCRIMINANT ADAPTIVE NEAREST NEIGHBOR

NEAREST NEIGHBOR CLASSIFIER

A special case of k-nn is the *nearest neighbor classifier* where $k = 1$ and the input is assigned to the class of the nearest pattern. This divides the space in the form of a *Voronoi tesselation* (see figure 8.5).

VORONOI TESSELATION

8.5 Condensed Nearest Neighbor

Time and space complexity of nonparametric methods are proportional to the size of the training set, and *condensing* methods have been proposed to decrease the number of stored instances without degrading performance. The idea is to select the smallest subset $\mathcal{Z}$ of $\mathcal{X}$ such that when $\mathcal{Z}$ is used in place of $\mathcal{X}$, error does not increase (Dasarathy 1991).

CONDENSED NEAREST NEIGHBOR

The best-known and earliest method is *condensed nearest neighbor* where 1-nn is used as the nonparametric estimator for classification (Hart

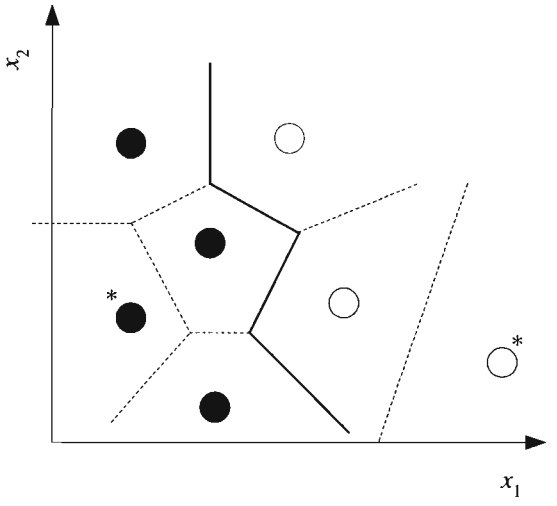

Figure 8.5 Dotted lines are the Voronoi tesselation and the straight line is the class discriminant. In condensed nearest neighbor, those instances that do not participate in defining the discriminant (marked by '*') can be removed without increasing the training error.

1968). 1-nn approximates the discriminant in a piecewise linear manner, and only the instances that define the discriminant need be kept; an instance inside the class regions need not be stored as *its* nearest neighbor is of the same class and its absence does not cause any error (on the training set) (figure 8.5). Such a subset is called a consistent subset, and we would like to find the minimal consistent subset.

Hart proposed a greedy algorithm to find $\mathcal{Z}$ (figure 8.6): The algorithm starts with an empty $\mathcal{Z}$ and passing over the instances in $\mathcal{X}$ one by one in a random order, checks if they can be classified correctly by 1-nn using the instances already stored in $\mathcal{Z}$. If an instance is misclassified, it is added to $\mathcal{Z}$; if it is correctly classified, $\mathcal{Z}$ is unchanged. One should pass over the training set a few times until no further instances are added. The algorithm does a local search and depending on the order in which the training instances are seen, different subsets may be found, which may have different accuracies on the validation data. Thus it does not guarantee finding the minimal consistent subset, which is known to be NP-complete (Wilfong 1992).

$\mathcal{Z} \leftarrow \emptyset$
Repeat
  For all $\boldsymbol{x} \in \mathcal{X}$ (in random order)
    Find $\boldsymbol{x}' \in \mathcal{Z}$ such that $\|\boldsymbol{x} - \boldsymbol{x}'\| = \min_{\boldsymbol{x}^j \in \mathcal{Z}} \|\boldsymbol{x} - \boldsymbol{x}^j\|$
    If class($\boldsymbol{x}$)≠class($\boldsymbol{x}'$) add $\boldsymbol{x}$ to $\mathcal{Z}$
Until $\mathcal{Z}$ does not change

Figure 8.6 Condensed nearest neighbor algorithm.

Condensed nearest neighbor is a greedy algorithm which aims to minimize training error and complexity, measured by the size of the stored subset. We can write an augmented error function

$$E'(\mathcal{Z}|\mathcal{X}) = E(\mathcal{X}|\mathcal{Z}) + \lambda|\mathcal{Z}| \tag{8.18}$$

where $E(\mathcal{X}|\mathcal{Z})$ is the error on $\mathcal{X}$ storing $\mathcal{Z}$. $|\mathcal{Z}|$ is the cardinality of $\mathcal{Z}$, and the second term penalizes complexity. As in any regularization scheme, λ represents the trade-off between the error and complexity such that for small λ, error becomes more important, and as λ gets larger, complex models are penalized more. Condensed nearest neighbor is one method to minimize equation 8.18, but other algorithms to optimize it can also be devised.

8.6 Nonparametric Regression: Smoothing Models

In regression, given the training set $\mathcal{X} = \{x^t, r^t\}$ where $r^t \in \Re$, we assume

$$r^t = g(x^t) + \epsilon$$

In parametric regression, we assume a polynomial of a certain order and compute its coefficients that minimize the sum of squared error on the training set. Nonparametric regression is used when no such polynomial can be assumed; we only assume that close x have close $g(x)$ values. As in nonparametric density estimation, given x, our approach is to find the neighborhood of x and average the r values in the neighborhood to calculate $\hat{g}(x)$. Nonparametric regression estimator is also called a *smoother* and the estimate is called a *smooth* (Härdle 1990). There are various methods for defining the neighborhood and averaging in the neighborhood, similar to methods in density estimation. We discuss the

SMOOTHER

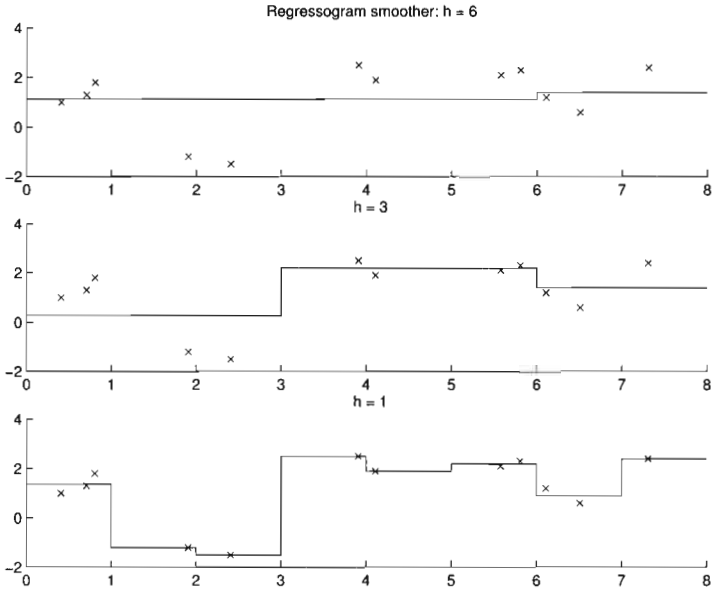

Figure 8.7 Regressograms for various bin lengths. '×' denote data points.

methods for the univariate x; they can be generalized to the multivariate case in a straightforward manner using multivariate kernels, as in density estimation.

8.6.1 Running Mean Smoother

If we define an origin and a bin width and average the r values in the bin as in the histogram, we get a *regressogram* (see figure 8.7)

REGRESSOGRAM

$$\hat{g}(x) = \frac{\sum_{t=1}^{N} b(x, x^t) r^t}{\sum_{t=1}^{N} b(x, x^t)} \tag{8.19}$$

where

$$b(x, x^t) = \begin{cases} 1 & \text{if } x^t \text{ is the same bin with } x \\ 0 & \text{otherwise} \end{cases}$$

Having discontinuities at bin boundaries is disturbing as is the need to fix an origin. As in the naive estimator, in the *running mean smoother*, we define a bin symmetric around x and average in there (figure 8.8).

RUNNING MEAN SMOOTHER

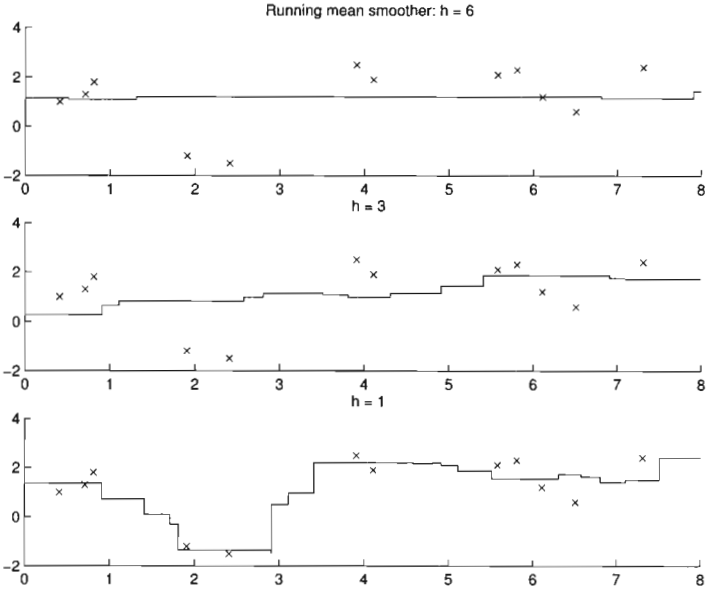

Figure 8.8 Running mean smooth for various bin lengths.

$$\hat{g}(x) = \frac{\sum_{t=1}^{N} w\left(\frac{x-x^t}{h}\right) r^t}{\sum_{t=1}^{N} w\left(\frac{x-x^t}{h}\right)} \tag{8.20}$$

where

$$w(u) = \begin{cases} 1 & \text{if } |u| < 1 \\ 0 & \text{otherwise} \end{cases}$$

This method is especially popular with evenly spaced data, for example, time series. In applications where there is noise, one can use the median of the r^t in the bin instead of their mean.

8.6.2 Kernel Smoother

KERNEL SMOOTHER

As in the kernel estimator, we can use a kernel giving less weight to further points, and we get the *kernel smoother* (see figure 8.9):

$$\hat{g}(x) = \frac{\sum_{t} K\left(\frac{x-x^t}{h}\right) r^t}{\sum_{t} K\left(\frac{x-x^t}{h}\right)} \tag{8.21}$$

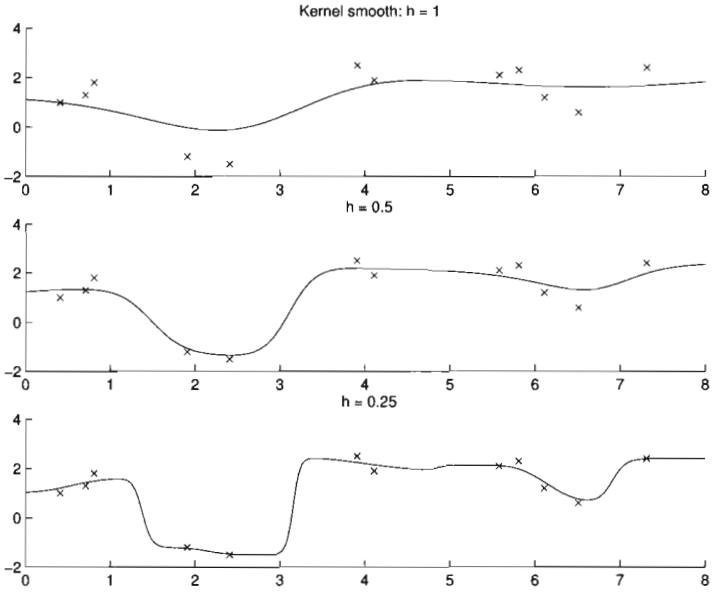

Figure 8.9 Kernel smooth for various bin lengths.

Typically a Gaussian kernel $K(\cdot)$ is used. Instead of fixing h, we can fix k, the number of neighbors, adapting the estimate to the density around x, and get the *k-nn smoother.*

k-NN SMOOTHER

8.6.3 Running Line Smoother

Instead of taking an average and giving a constant fit at a point, we can take into account one more term in the Taylor expansion and calculate a linear fit. In the *running line smoother,* we can use the data points in the neighborhood, as defined by h or k, and fit a local regression line (see figure 8.10).

RUNNING LINE SMOOTHER

In the *locally weighted running line smoother,* known as *loess,* instead of a hard definition of neighborhoods, we use kernel weighting such that distant points have less effect on error.

LOCALLY WEIGHTED RUNNING LINE SMOOTHER

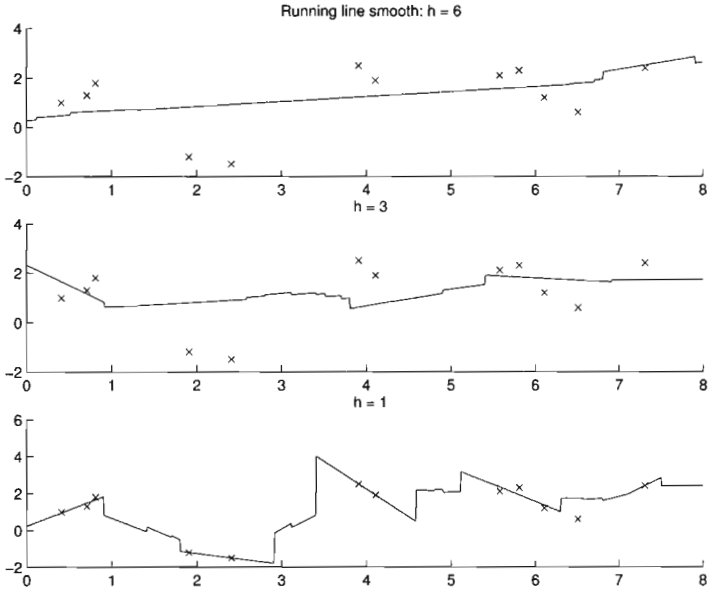

Figure 8.10 Running line smooth for various bin lengths.

8.7 How to Choose the Smoothing Parameter

In nonparametric methods, for density estimation or regression, the critical parameter is the smoothing parameter as used in bin width or kernel spread h, or the number of neighbors k. The aim is to have an estimate that is less variable than the data points. As we have discussed previously, one source of variability in the data is noise and the other is the variability in the unknown underlying function. We should smooth just enough to get rid of the effect of noise—not less, not more. With too large h or k, many instances contribute to the estimate at a point and we also smooth the variability due to the function and there is oversmoothing; with too small h or k, single instances have a large effect, we do not even smooth over the noise and there is undersmoothing. In other words, small h or k leads to small bias but large variance. Larger h or k decreases variance but increases bias. Geman, Bienenstock, and Doursat (1992) discuss bias and variance for nonparametric estimators.

SMOOTHING SPLINES

This requirement is explicitly coded in a regularized cost function as used in *smoothing splines*

$$\sum_t [r^t - \hat{g}(x^t)]^2 + \lambda \int_a^b [\hat{g}''(x)]^2 dx \tag{8.22}$$

The first term is the error of fit. $[a, b]$ is the input range; $\hat{g}''(\cdot)$ is the *curvature* of the estimated function $\hat{g}(\cdot)$ and as such measures the variability. Thus the second term penalizes fast varying estimates. λ trades off variability and error where, for example, with large λ, we get smoother estimates.

Cross-validation is used to tune h, k, or λ. In density estimation, we choose the parameter value that maximizes the likelihood of the validation set. In a supervised setting, trying a set of candidates on the training set, we choose the parameter value that minimizes the error on the validation set.

8.8 Notes

k-nearest neighbor and kernel-based estimation were proposed fifty years ago, but because of the need for large memory and computation, the approach was not popular until recently (Aha, Kibler, and Albert 1991). With advances in parallel processing and with memory and computation getting cheaper, such methods have recently become more widely used. Textbooks on nonparametric estimation are Silverman 1986 and Scott 1992. Dasarathy 1991 is a collection of many papers on k-nn and editing/condensing rules; Aha 1997 is a collection of more recent work.

The nonparametric methods are very easy to parallelize on a Single Instruction Multiple Data (SIMD) machine; each processor stores one training instance in its local memory and in parallel computes the kernel function value for that instance (Stanfill and Waltz 1986). Multiplying with a kernel function can be seen as a convolution, and we can use Fourier transformation to calculate the estimate more efficiently (Silverman 1986). It has also been shown that spline smoothing is equivalent to kernel smoothing.

The most critical factor in nonparametric estimation is the distance metric used. With discrete attributes, we can simply use the Hamming distance where we just sum up the number of nonmatching attributes. More sophisticated distance functions are discussed in Wettschereck, Aha, and Mohri 1997 and Webb 1999.

CASE-BASED REASONING

In artificial intelligence, the nonparametric approach is called *case-based reasoning*. The output is found by interpolating from known sim-

ilar past "cases." This also allows for some knowledge extraction: The given output can be justified by listing these similar past cases.

Due to its simplicity, k-nn is the most widely used nonparametric classification method and is quite successful in practice in a variety of applications. It has been shown (Cover and Hart 1967; reviewed in Duda, Hart, and Stork 2001) that in the large sample case when $N \to \infty$, the risk of nearest neighbor ($k = 1$) is never worse than twice the Bayes' risk (which is the best that can be achieved) and in that respect, it is said that "half of the available information in an infinite collection of classified samples is contained in the nearest neighbor" (Cover and Hart 1967, 21). In the case of k-nn, it has been shown that the risk asymptotes to the Bayes' risk as k goes to infinity.

ADDITIVE MODELS

Nonparametric regression is discussed in detail in Härdle 1990. Hastie and Tibshirani (1990) discuss smoothing models and propose *additive models* where a multivariate function is written as a sum of univariate estimates. Locally weighted regression is discussed in Atkeson, Moore, and Schaal 1997. These models bear much similarity to radial basis functions and mixture of experts that we will discuss in chapter 12.

8.9 Exercises

1. Show equation 8.17.
2. How does condensed nearest neighbor behave if $k > 1$?
3. In a regressogram, instead of averaging in a bin and doing a constant fit, one can use the instances falling in a bin and do a linear fit (see figure 8.11). Write the code and compare this with the regressogram proper.
4. Write the error function for loess discussed in section 8.6.3.
5. Propose an incremental version of the running mean estimator, which, like the condensed nearest neighbor, stores instances only when necessary.
6. Generalize kernel smoother to multivariate data.

9 Decision Trees

A decision tree is a hierarchical data structure implementing the divide-and-conquer strategy. It is an efficient nonparametric method, which can be used both for classification and regression. We discuss learning algorithms that build the tree from a given labeled training sample, as well as how the tree can be converted to a set of simple rules that are easy to understand.

9.1 Introduction

IN PARAMETRIC estimation, we define a model over the whole input space and learn its parameters from all of the training data. Then we use the same model and the same parameter set for any test input. In nonparametric estimation, we divide the input space into local regions, defined by a distance measure like the Euclidean norm, and for each input, the corresponding local model computed from the training data in that region is used. In nonparametric models, given an input, identifying the local data defining the local model is costly; it requires calculating the distances from the given input to all of the training instances, which is $\mathcal{O}(N)$.

DECISION TREE

A *decision tree* is a hierarchical model for supervised learning whereby the local region is identified in a sequence of recursive splits in a smaller number of steps. A decision tree is composed of internal decision nodes and terminal leaves (see figure 9.1). Each *decision node* m implements a test function $f_m(\boldsymbol{x})$ with discrete outcomes labeling the branches. Given an input, at each node, a test is applied and one of the branches is taken depending on the outcome. This process starts at the root and is repeated recursively until a *leaf node* is hit, at which point the value written in the

DECISION NODE

LEAF NODE

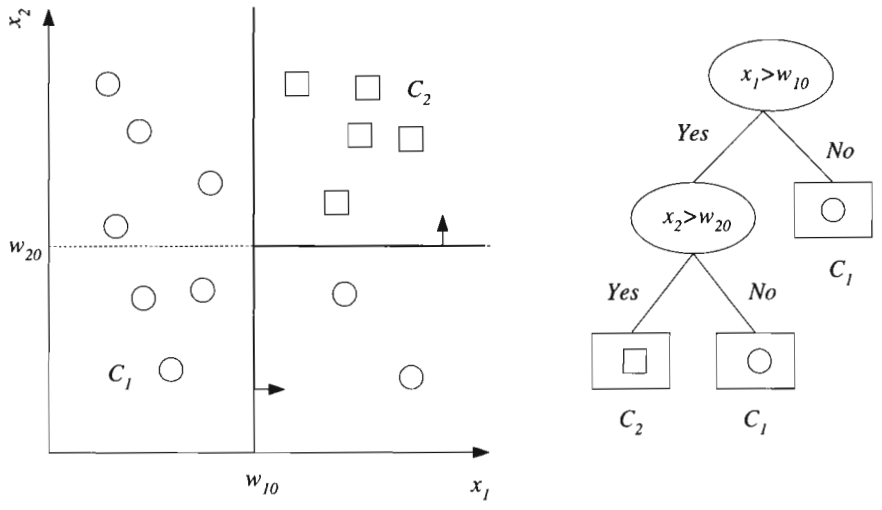

Figure 9.1 Example of a dataset and the corresponding decision tree. Oval nodes are the decision nodes and rectangles are leaf nodes. The univariate decision node splits along one axis, and successive splits are orthogonal to each other. After the first split, $\{\boldsymbol{x}|x_1 < w_{10}\}$ is pure and is not split further.

leaf constitutes the output.

Each $f_m(\boldsymbol{x})$ defines a discriminant in the d-dimensional input space dividing it into smaller regions which are further subdivided as we take a path from the root down. $f_m(\cdot)$ is a simple function and when written down as a tree, a complex function is broken down into a series of simple decisions. Different decision tree methods assume different models for $f_m(\cdot)$, and the model class defines the shape of the discriminant and the shape of regions. Each leaf node has an output label, which in the case of classification is the class code and in regression is a numeric value. A leaf node defines a localized region in the input space where instances falling in this region have the same output. The boundaries of the regions are defined by the discriminants that are coded in the internal nodes on the path from the root to the leaf node.

The hierarchical placement of decisions allows a fast localization of the region covering an input. For example, if the decisions are binary, then in the best case, each decision eliminates half of the cases. If there are b regions, then in the best case, the correct region can be found in $\log_2 b$

decisions. Another advantage of the decision tree is interpretability: As we will see shortly, the tree can be converted to a set of *IF-THEN rules* that are easily understandable. For this reason, decision trees are very popular and sometimes preferred over more accurate but less interpretable methods.

We start with univariate trees where the test in a decision node uses only one input variable and we see how such trees can be constructed for classification and regression. We later generalize this to multivariate trees where all inputs can be used in an internal node.

9.2 Univariate Trees

UNIVARIATE TREE

In a *univariate tree,* in each internal node, the test uses only one of the input dimensions. If the used input dimension, x_j, is discrete, taking one of n possible values, the decision node checks the value of x_j and takes the corresponding branch, implementing an n-way split. For example, if an attribute is color with possible values {red, blue, green}, then a node on that attribute has three branches, each one corresponding to one of the three possible values of the attribute.

A decision node has discrete branches and a numeric input should be discretized. If x_j is numeric (ordered), the test is a comparison

$$f_m(\mathbf{x}) : x_j \geq w_{m0} \tag{9.1}$$

where w_{m0} is a suitably chosen threshold value. The decision node divides the input space into two: $L_m = \{\mathbf{x}|x_j \geq w_{m0}\}$ and $R_m = \{\mathbf{x}|x_j < w_{m0}\}$; this is called a *binary split.* Successive decision nodes on a path from the root to a leaf further divide these into two using other attributes and generating splits orthogonal to each other. The leaf nodes define hyperrectangles in the input space (see figure 9.1).

BINARY SPLIT

Tree induction is the construction of the tree given a training sample. For a given training set, there exists many trees that code it with no error, and, for simplicity, we are interested in finding the smallest among them, where tree size is measured as the number of nodes in the tree and the complexity of the decision nodes. Finding the smallest tree is NP-complete (Quinlan 1986), and we are forced to use local search procedures based on heuristics that give reasonable trees in reasonable time.

Tree learning algorithms are greedy and, at each step, starting at the root with the complete training data, we look for the best split. This

splits the training data into two or n, depending on whether the chosen attribute is numeric or discrete. We then continue splitting recursively with the corresponding subset until we do not need to split anymore, at which point a leaf node is created and labeled.

9.2.1 Classification Trees

CLASSIFICATION TREE
IMPURITY MEASURE

In the case of a decision tree for classification, namely, a *classification tree*, the goodness of a split is quantified by an *impurity measure*. A split is pure if after the split, for all branches, all the instances choosing a branch belong to the same class. Let us say for node m, N_m is the number of training instances reaching node m. For the root node, it is N. N_m^i of N_m belong to class C_i, with $\sum_i N_m^i = N_m$. Given that an instance reaches node m, the estimate for the probability of class C_i is

$$\hat{P}(C_i|\mathbf{x}, m) \equiv p_m^i = \frac{N_m^i}{N_m} \tag{9.2}$$

Node m is pure if p_m^i for all i are either 0 or 1. It is 0 when none of the instances reaching node m are of class C_i, and it is 1 if all such instances are of C_i. If the split is pure, we do not need to split any further and can add a leaf node labeled with the class for which p_m^i is 1. One possible function to measure impurity is *entropy* (Quinlan 1986) (see figure 9.2)

ENTROPY

$$\mathcal{I}_m = -\sum_{i=1}^{K} p_m^i \log_2 p_m^i \tag{9.3}$$

where $0 \log 0 \equiv 0$. Entropy in information theory specifies the minimum number of bits needed to encode the classification accuracy of an instance. In a two-class problem, if $p^1 = 1$ and $p^2 = 0$, all examples are of C^1, and we do not need to send anything, and the entropy is 0. If $p^1 = p^2 = 0.5$, we need to send a bit to signal one of the two cases, and the entropy is 1. In between these two extremes, we can devise codes and use less than a bit per message by having shorter codes for the more likely class and longer codes for the less likely. When there are $K > 2$ classes, the same discussion holds and the largest entropy is $\log_2 K$ when $p^i = 1/K$.

But entropy is not the only possible measure. For a two-class problem where $p^1 \equiv p$ and $p^2 = 1 - p$, $\phi(p, 1-p)$ is a nonnegative function measuring the impurity of a split if it satisfies the following properties (Devroye, Györfi, and Lugosi 1996):

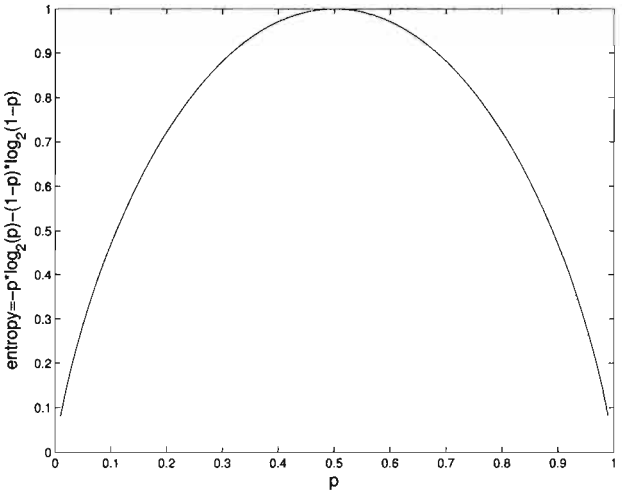

Figure 9.2 Entropy function for a two-class problem.

- $\phi(1/2, 1/2) \geq \phi(p, 1-p)$, for any $p \in [0, 1]$.
- $\phi(0, 1) = \phi(1, 0) = 0$.
- $\phi(p, 1-p)$ is increasing in p on $[0, 1/2]$ and decreasing in p on $[1/2, 1]$.

Examples are

1. Entropy

$$\phi(p, 1-p) = -p \log_2 p - (1-p) \log_2 (1-p) \tag{9.4}$$

Equation 9.3 is the generalization to $K > 2$ classes.

GINI INDEX 2. *Gini index* (Breiman et al. 1984)

$$\phi(p, 1-p) = 2p(1-p) \tag{9.5}$$

3. Misclassification error

$$\phi(p, 1-p) = 1 - \max(p, 1-p) \tag{9.6}$$

These can be generalized to $K > 2$ classes, and the misclassification error can be generalized to minimum risk given a loss function (exercise 1). Research has shown that there is not a significant difference between these three measures.

If node m is not pure, then the instances should be split to decrease impurity, and there are multiple possible attributes on which we can split. For a numeric attribute, multiple split positions are possible. Among all, we look for the split that minimizes impurity after the split because we want to generate the smallest tree. If the subsets after the split are closer to pure, fewer splits (if any) will be needed afterward. Of course this is locally optimal, and we have no guarantee of finding the smallest decision tree.

Let us say at node m, N_{mj} of N_m take branch j; these are $\mathbf{x}^t$ for which the test $f_m(\mathbf{x}^t)$ returns outcome j. For a discrete attribute with n values, there are n outcomes, and for a numeric attribute, there are two outcomes ($n = 2$), in either case satisfying $\sum_{j=1}^{n} N_{mj} = N_m$. N_{mj}^i of N_{mj} belong to class C_i: $\sum_{i=1}^{K} N_{mj}^i = N_{mj}$. Similarly, $\sum_{j=1}^{n} N_{mj}^i = N_m^i$.

Then given that at node m, the test returns outcome j, the estimate for the probability of class C_i is

$$\hat{P}(C_i|\mathbf{x}, m, j) \equiv p_{mj}^i = \frac{N_{mj}^i}{N_{mj}} \tag{9.7}$$

and the total impurity after the split is given as

$$\mathcal{I}'_m = -\sum_{j=1}^{n} \frac{N_{mj}}{N_m} \sum_{i=1}^{K} p_{mj}^i \log p_{mj}^i \tag{9.8}$$

In the case of a numeric attribute, to be able to calculate p_{mj}^i using equation 9.1, we also need to know w_{m0} for that node. There are $N_m - 1$ possible w_{m0} between N_m data points: We do not need to test for all (possibly infinite) points; it is enough to test, for example, at halfway between points. Note also that the best split is always between adjacent points belonging to different classes. So we try them, and the best in terms of purity is taken for the purity of the attribute. In the case of a discrete attribute, no such iteration is necessary.

So for all attributes, discrete and numeric, and for a numeric attribute for all split positions, we calculate the impurity and choose the one that has the minimum entropy, for example, as measured by equation 9.8. Then tree construction continues recursively and in parallel for all the

```

branches that are not pure, until all are pure. This is the basis of the *Classification and Regression Trees* (CART) algorithm (Breiman et al. 1984), *ID3* algorithm (Quinlan 1986), and its extension *C4.5* (Quinlan 1993). The pseudocode of the algorithm is given in figure 9.3.

It can also be said that at each step during tree construction, we choose the split that causes the largest decrease in impurity, which is the difference between the impurity of data reaching node m (equation 9.3) and the total entropy of data reaching its branches after the split (equation 9.8).

One problem is that such splitting favors attributes with many values. When there are many values, there are many branches, and the impurity can be much less. For example, if we take training index t as an attribute, the impurity measure will choose that because then the impurity of each branch is 0, although it is not a reasonable feature. Nodes with many

branches are complex and go against our idea of splitting class discriminants into simple decisions. Methods have been proposed to penalize such attributes and to balance the impurity drop and the branching factor.

When there is noise, growing the tree until it is purest, we may grow a very large tree and it overfits; for example, consider the case of a mislabeled instance amid a group of correctly labeled instances. To alleviate such overfitting, tree construction ends when nodes become pure enough, namely, a subset of data is not split further if $\mathcal{I} < \theta_I$. This implies that we do not require that p^i_{mj} be exactly 0 or 1 but close enough, with a threshold θ_p. In such a case, a leaf node is created and is labeled with the class having the highest p^i_{mj}.

θ_I (or θ_p) is the complexity parameter, like h or k of nonparametric estimation. When they are small, the variance is high and the tree grows large to reflect the training set accurately, and when they are large, variance is lower and a smaller tree roughly represents the training set and may have large bias. The ideal value depends on the cost of misclassification, as well as the costs of memory and computation.

It is generally advised that in a leaf, one stores the posterior probabilities of classes, instead of labeling the leaf with the class having the highest posterior. These probabilities may be required in later steps, for example, in calculating risks. Note that we do not need to store the instances reaching the node or the exact counts; just ratios suffice.

9.2.2 Regression Trees

REGRESSION TREE

A *regression tree* is constructed in almost the same manner as a classification tree, except that the impurity measure that is appropriate for classification is replaced by a measure appropriate for regression. Let us say for node m, $\mathcal{X}_m$ is the subset of $\mathcal{X}$ reaching node m, namely, it is the set of all $\mathbf{x} \in \mathcal{X}$ satisfying all the conditions in the decision nodes on the path from the root until node m. We define

$$b_m(\mathbf{x}) = \begin{cases} 1 & \text{if } \mathbf{x} \in \mathcal{X}_m\text{: } \mathbf{x} \text{ reaches node } m \\ 0 & \text{otherwise} \end{cases} \tag{9.9}$$

In regression, the goodness of a split is measured by the mean square error from the estimated value. Let us say g_m is the estimated value in

node m.

$$E_m = \frac{1}{N_m} \sum_t (r^t - g_m)^2 b_m(\mathbf{x}^t) \tag{9.10}$$

where $N_m = |\mathcal{X}_m| = \sum_t b_m(\mathbf{x}^t)$.

In a node, we use the mean (median if there is too much noise) of the required outputs of instances reaching the node

$$g_m = \frac{\sum_t b_m(\mathbf{x}^t) r^t}{\sum_t b_m(\mathbf{x}^t)} \tag{9.11}$$

Then equation 9.10 corresponds to the variance at m. If at a node, the error is acceptable, that is, $E_m < \theta_r$, then a leaf node is created and it stores the g_m value. Just like the regressogram of chapter 8, this creates a piecewise constant approximation with discontinuities at leaf boundaries.

If the error is not acceptable, data reaching node m is split further such that the sum of the errors in the branches is minimum. As in classification, at each node, we look for the attribute (and split threshold for a numeric attribute) that minimizes the error, and then we continue recursively.

Let us define $\mathcal{X}_{mj}$ as the subset of $\mathcal{X}_m$ taking branch j: $\cup_{j=1}^n \mathcal{X}_{mj} = \mathcal{X}_m$. We define

$$b_{mj}(\mathbf{x}) = \begin{cases} 1 & \text{if } \mathbf{x} \in \mathcal{X}_{mj}\text{: } \mathbf{x} \text{ reaches node } m \text{ and takes branch } j \\ 0 & \text{otherwise} \end{cases} \tag{9.12}$$

g_{mj} is the estimated value in branch j of node m.

$$g_{mj} = \frac{\sum_t b_{mj}(\mathbf{x}^t) r^t}{\sum_t b_{mj}(\mathbf{x}^t)} \tag{9.13}$$

and the error after the split is

$$E'_m = \frac{1}{N_m} \sum_j \sum_t (r^t - g_{mj})^2 b_{mj}(\mathbf{x}^t) \tag{9.14}$$

The drop in error for any split is given as the difference between equation 9.10 and equation 9.14. We look for the split such that this drop is maximum or, equivalently, where equation 9.14 takes its minimum. The code given in figure 9.3 can be adapted to training a regression tree by replacing entropy calculations with mean square error and class labels with averages.

Mean square error is one possible error function; another is worst possible error

$$E_m = \max_j \max_t |r^t - g_{mj}| b_m(\boldsymbol{x}^t) \tag{9.15}$$

using which we can guarantee that the error for any instance is never larger than a given threshold.

The acceptable error threshold is the complexity parameter; when it is small, we generate large trees and risk overfitting; when it is large, we underfit and smooth too much (see figures 9.4 and 9.5).

Similar to going from running mean to running line in nonparametric regression, instead of taking an average at a leaf that implements a constant fit, we can also do a linear regression fit over the instances choosing the leaf:

$$g_m(\boldsymbol{x}) = \boldsymbol{w}_m^T \boldsymbol{x} + w_{m0} \tag{9.16}$$

This makes the estimate in a leaf dependent on $\boldsymbol{x}$ and generates smaller trees but there is the expense of extra computation at a leaf node.

9.3 Pruning

Frequently, a node is not split further if the number of training instances reaching a node is smaller than a certain percentage of the training set, for example, 5 percent, regardless of the impurity or error. The idea is that any decision based on too few instances causes variance and thus generalization error. Stopping tree construction early on before it is full is called *prepruning* the tree.

PREPRUNING

POSTPRUNING

Another possibility to get simpler trees is *postpruning*, which in practice works better than prepruning. We saw before that tree growing is greedy where at each step, we make a decision, namely, generate a decision node, and continue further on, never backtracking and trying out an alternative. The only exception is postpruning where we try to find and prune unnecessary subtrees.

In postpruning, we grow the tree full until all leaves are pure and we have zero training error. We then find subtrees that cause overfitting and we prune them. From the initial labeled set, we set aside a *pruning set*, unused during training. For each subtree, we replace it by a leaf node labeled with the training instances covered by the subtree (appropriately for classification or regression). If the leaf node does not perform worse

PRUNING SET

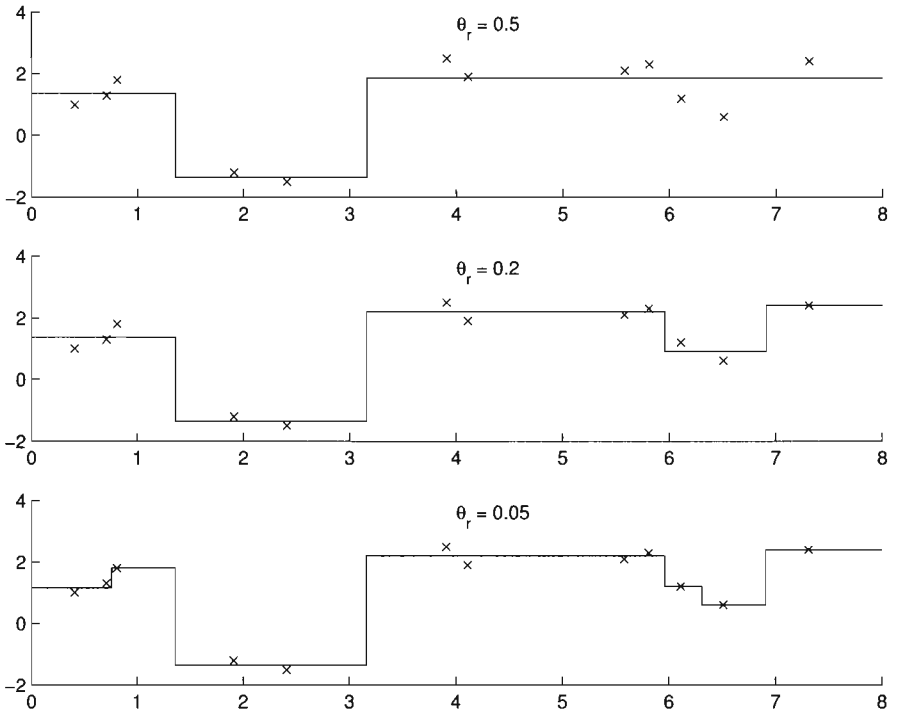

Figure 9.4 Regression tree smooths for various values of θ_r. The corresponding trees are given in figure 9.5.

than the subtree on the pruning set, we prune the subtree and keep the leaf node because the additional complexity of the subtree is not justified; otherwise, we keep the subtree.

For example, in the third tree of figure 9.5, there is a subtree starting with condition $x < 6.31$. This subtree can be replaced by a leaf node of $y = 0.9$ (as in the second tree) if the error on the pruning set does not increase during the substitution. Note that the pruning set should not be confused with (and is distinct from) the validation set.

Comparing prepruning and postpruning, we can say that prepruning is faster but postpruning generally leads to more accurate trees.

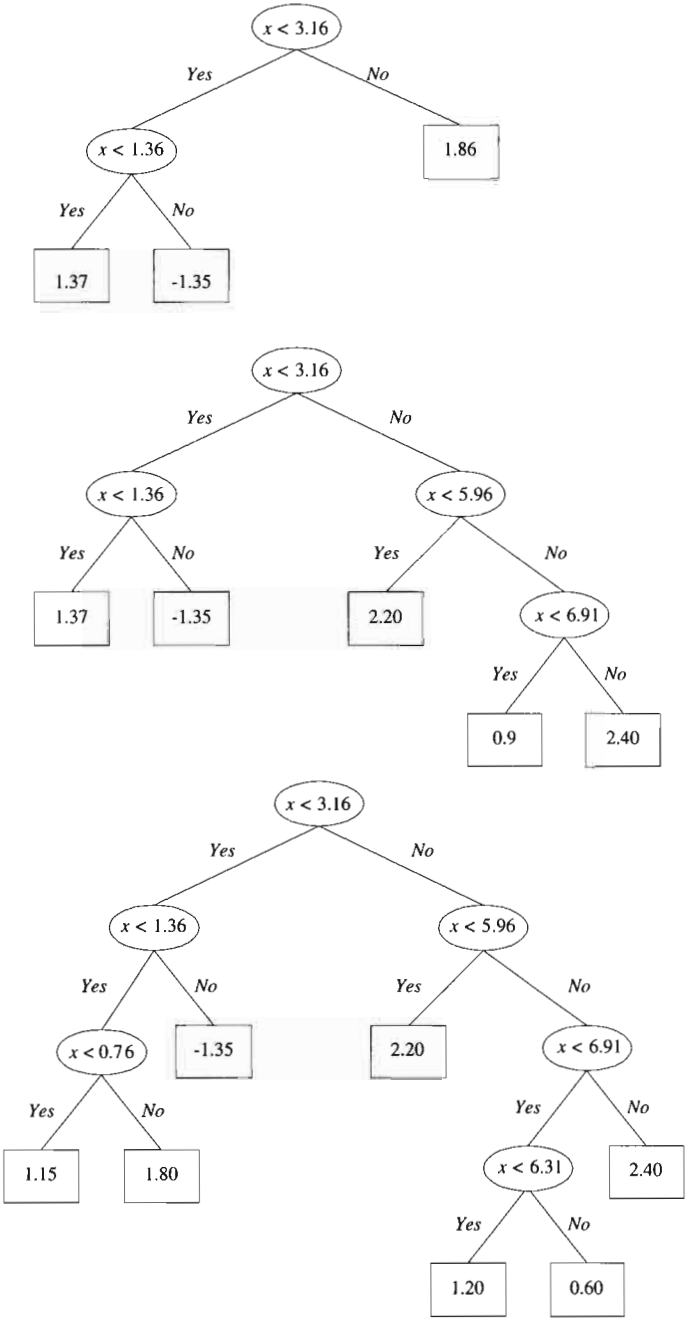

Figure 9.5 Regression trees implementing the smooths of figure 9.4 for various values of θ_r.

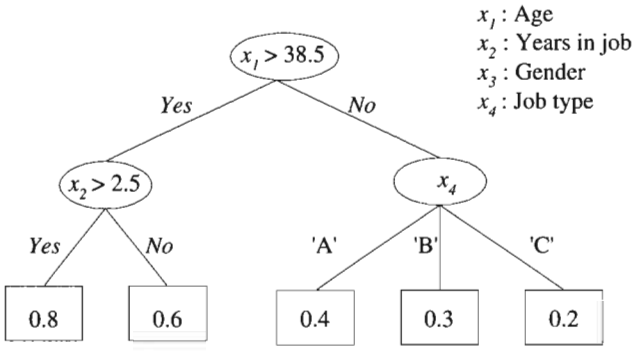

Figure 9.6 Example of a (hypothetical) decision tree. Each path from the root to a leaf can be written down as a conjunctive rule, composed of conditions defined by the decision nodes on the path.

9.4 Rule Extraction from Trees

A decision tree does its own feature extraction. The univariate tree only uses the variables that are necessary, and it may be the case that after the tree is built, certain features are not used at all. We can also say that features closer to the root are more important globally. For example, the decision tree given in figure 9.6 uses x_1, x_2, and x_4, but not x_3. It is possible to use a decision tree for feature extraction: We build a tree and then take only those features used by the tree as inputs to another learning method.

INTERPRETABILITY

Another main advantage of decision trees is *interpretability:* The decision nodes carry conditions that are simple to understand. Each path from the root to a leaf corresponds to one conjunction of tests, as all those conditions should be satisfied to reach to the leaf. These paths together can be written down as a set of *IF-THEN rules,* called a *rule base.* One such method is *C4.5Rules* (Quinlan 1993).

IF-THEN RULES

For example, the decision tree of figure 9.6 can be written down as the following set of rules:

R1: IF (age>38.5) AND (years-in-job>2.5) THEN y =0.8
R2: IF (age>38.5) AND (years-in-job≤2.5) THEN y =0.6
R3: IF (age≤38.5) AND (job-type='A') THEN y =0.4
R4: IF (age≤38.5) AND (job-type='B') THEN y =0.3
R5: IF (age≤38.5) AND (job-type='C') THEN y =0.2

KNOWLEDGE EXTRACTION

Such a rule base allows *knowledge extraction;* it can be easily understood and allows experts to verify the model learned from data. For each rule, one can also calculate the percentage of training data covered by the rule, namely, *rule support.* The rules reflect the main characteristics of the dataset: They show the important features and split positions. For example, in this (hypothetical) example, we see that in terms of our purpose (y), people who are thirty-eight years old or less are different from people who are thirty-nine or more years old. And among this latter group, it is the job type that makes them different, whereas in the former group, it is the number of years in a job that is the best discriminating characteristic.

RULE SUPPORT

In the case of a classification tree, there may be more than one leaf labeled with the same class. In such a case, these multiple conjunctive expressions corresponding to different paths can be combined as a disjunction (OR). The class region then corresponds to a union of these multiple patches, each patch corresponding to the region defined by one leaf. For example, class C_1 of figure 9.1 is written as

$$\text{IF } (x \leq w_{10}) \text{ OR } ((x_1 > w_{10}) \text{ AND } (x_2 \leq w_{20})) \text{ THEN } C_1$$

PRUNING RULES

Pruning rules is possible for simplification. Pruning a subtree corresponds to pruning terms from a number of rules at the same time. It may be possible to prune a term from one rule without touching other rules. For example, in the previous rule set, for R3, if we see that all whose `job-type='A'` have outcomes close to 0.4, regardless of `age`, $R3$ can be pruned as

$$R3' : \text{IF (job-type='A') THEN } y = 0.4$$

Note that after the rules are pruned, it may not be possible to write them back as a tree anymore.

9.5 Learning Rules from Data

RULE INDUCTION

As we have just seen, one way to get IF-THEN rules is to train a decision tree and convert it to rules. Another is to learn the rules directly. *Rule induction* works similar to tree induction except that rule induction does a depth-first search and generates one path (rule) at a time, whereas tree induction goes breadth-first and generates all paths simultaneously.

Rules are learned one at a time. Each rule is a conjunction of conditions on discrete or numeric attributes (as in decision trees) and these

conditions are added one at a time, to optimize some criterion, for example, minimize entropy. A rule is said to *cover* an example if the example satisfies all the conditions of the rule. Once a rule is grown and pruned, it is added to the rule base and all the training examples covered by the rule are removed from the training set, and the process continues until enough rules are added. This is called *sequential covering*. There is an outer loop of adding one rule at a time to the rule base and an inner loop of adding one condition at a time to the current rule. These steps are both greedy and do not guarantee optimality. Both loops have a pruning step for better generalization.

SEQUENTIAL COVERING

RIPPER
IREP

One example of a rule induction algorithm is *Ripper* (Cohen 1995), based on an earlier algorithm *Irep* (Fürnkrantz and Widmer 1994). We start with the case of two classes where we talk of positive and negative examples, then later generalize to $K > 2$ classes. Rules are added to explain positive examples such that if an instance is not covered by any rule, then it is classified as negative. So a rule when it matches is either correct (true positive), or it causes a false positive. The pseudocode of the outer loop of Ripper is given in figure 9.7.

FOIL

In Ripper, conditions are added to the rule to maximize an information gain measure used in Quinlan's (1990) *Foil* algorithm. Let us say we have rule R and R' is the candidate rule after adding a condition. Change in gain is defined as

$$Gain(R', R) = s \cdot \left(\log_2 \frac{N'_+}{N'} - \log_2 \frac{N_+}{N} \right) \tag{9.17}$$

where N is the number of instances that are covered by R and N_+ is the number of true positives in them. N' and N'_+ are similarly defined for R'. s is the number of true positives in R, which are still true positives in R', after adding the condition. In terms of information theory, the change in gain measures the reduction in bits to encode a positive instance.

Conditions are added to a rule until it covers no negative example. Once a rule is grown, it is pruned back by deleting conditions in reverse order, to find the rule that maximizes the *rule value metric*

RULE VALUE METRIC

$$rvm(R) = \frac{p - n}{p + n} \tag{9.18}$$

where p and n are the number of true and false positives respectively, on the pruning set, which is one-third of the data, having used two-thirds as the growing set.

    Return RuleSet
```

Figure 9.7 Ripper algorithm for learning rules. Only the outer loop is given; the inner loop is similar to adding nodes in a decision tree.

Once a rule is grown and pruned, all positive and negative training examples covered by the rule are removed from the training set. If there are remaining positive examples, rule induction continues. In the case of noise, we may stop early, namely, when a rule does not explain enough number of examples. To measure the worth of a rule, minimum description length (section 4.8) is used (Quinlan 1995). Typically, we stop if the description of the rule is not shorter than the description of instances it explains. The description length of a rule base is the sum of the description lengths of all the rules in the rule base, plus the description of instances not covered by the rule base. Ripper stops adding rules when the description length of the rule base is more than 64 bits larger than the best description length so far. Once the rule base is learned, we pass over the rules in reverse order to see if they can be removed without increasing the description length.

Rules in the rule base are also optimized after they are learned. Ripper considers two alternatives to a rule: One, called the replacement rule, starts from an empty rule, is grown, and is then pruned. The second, called the revision rule, starts with the rule as it is, is grown, and is then pruned. These two are compared with the original rule, and the shortest of three is added to the rule base. This optimization of the rule base can be done k times, typically twice.

When there are $K > 2$ classes, they are ordered in terms of their prior probabilities such that C_1 has the lowest prior probability and C_K has the highest. Then a sequence of two-class problems are defined such that first, instances belonging to C_1 are taken as positive examples and instances of all other classes are taken as examples. Then, having learned C_1 and all its instances removed, it learns to separate C_2 from $C_3, \ldots, C_K$. This process is repeated until only C_K remains. The empty default rule is then labeled C_K, so that if an instance is not covered by any rule, it will be assigned to C_K.

For a training set of size N, Ripper's complexity is $\mathcal{O}(N \log^2 N)$ and is an algorithm that can be used on very large training sets (Dietterich 1997). The rules we learn are *propositional rules.* More expressive, *first-order rules* have variables in conditions, called *predicates.* A *predicate* is a function that returns true or false depending on the value of its argument. Predicates therefore allow defining relations between the values of attributes, which cannot be done by propositions (Mitchell 1997):

PROPOSITIONAL RULES
FIRST-ORDER RULES

IF Father(y, x) AND Female(y) THEN Daughter(x, y)

INDUCTIVE LOGIC PROGRAMMING

Such rules can be seen as programs in a logic programming language, such as Prolog, and learning them from data is called *inductive logic programming.* One such algorithm is *Foil* (Quinlan 1990).

BINDING

Assigning a value to a variable is called *binding.* A rule matches if there is a set of bindings to the variables existing in the training set. Learning first-order rules is similar to learning propositional rules with an outer loop of adding rules, and an inner loop of adding conditions to a rule, with prunings at the end of each loop. The difference is in the inner loop, where at each step we consider one predicate to add (instead of a proposition) and check the increase in the performance of the rule (Mitchell 1997). To calculate the performance of a rule, we consider all possible bindings of the variables, count the number of positive and negative bindings in the training set, and use, for example, equation 9.17. In this first-order case, we have predicates instead of propositions, so they should be previously defined, and the training set is a set of predicates known to be true.

9.6 Multivariate Trees

MULTIVARIATE TREE

In the case of a univariate tree, only one input dimension is used at a split. In a *multivariate tree,* at a decision node, all input dimensions can be used and thus it is more general. When all inputs are numeric, a binary linear multivariate node is defined as

$$f_m(\mathbf{x}) : \mathbf{w}_m^T \mathbf{x} + w_{m0} > 0 \tag{9.19}$$

Because the linear multivariate node takes a weighted sum, discrete attributes should be represented by 0/1 dummy numeric variables. Equation 9.19 defines a hyperplane with arbitrary orientation (see figure 9.8). Successive nodes on a path from the root to a leaf further divide these and leaf nodes define polyhedra in the input space. The univariate node with a numeric feature is a special case when all but one of w_{mj} are 0. Thus the univariate numeric node of equation 9.1 also defines a linear discriminant but one that is orthogonal to axis x_j, intersecting it at w_{m0} and parallel to all other x_i. We therefore see that in a univariate node there are d possible orientations ($\mathbf{w}_m$) and $N_m - 1$ possible thresholds ($-w_{m0}$), making an exhaustive search possible. In a multivariate node, there are $2^d \begin{pmatrix} N_m \\ d \end{pmatrix}$ possible hyperplanes (Murthy, Kasif, and Salzberg 1994) and an exhaustive search is no longer possible.

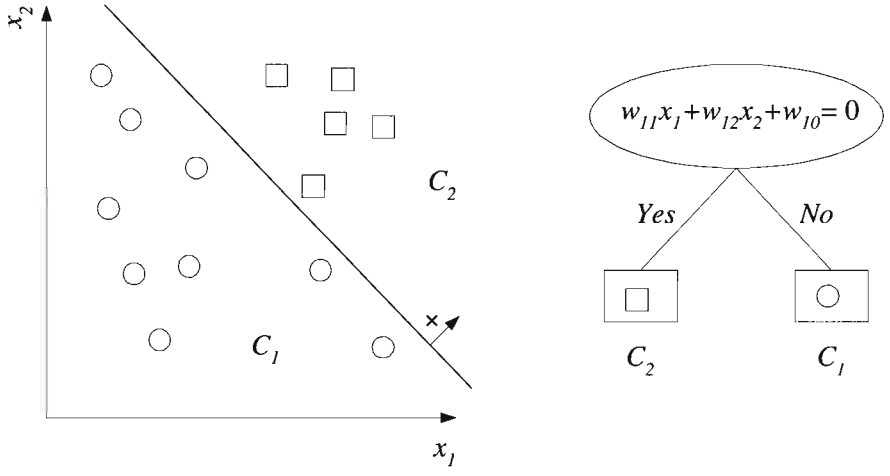

Figure 9.8 Example of a linear multivariate decision tree. The linear multivariate node can place an arbitrary hyperplane thus is more general, whereas the univariate node is restricted to axis-aligned splits.

When we go from a univariate node to a linear multivariate node, the node becomes more flexible. It is possible to make it even more flexible by using a nonlinear multivariate node. For example, with a quadratic, we have

$$f_m(\mathbf{x}) : \mathbf{x}^T \mathbf{W}_m \mathbf{x} + \mathbf{w}_m^T \mathbf{x} + w_{m0} > 0 \tag{9.20}$$

Guo and Gelfand (1992) propose to use a multilayer perceptron (chapter 11) that is a linear sum of nonlinear basis functions, and this is another way of having nonlinear decision nodes. Another possibility is a

SPHERE NODE *sphere node* (Devroye, Györfi, and Lugosi 1996)

$$f_m(\mathbf{x}) : \|\mathbf{x} - \mathbf{c}_m\| \leq \alpha_m \tag{9.21}$$

where $\mathbf{c}_m$ is the center and α_m is the radius.

There are a number of algorithms proposed for learning multivariate decision trees for classification: The earliest is the multivariate version of

CART the *CART* algorithm (Breiman et al. 1984), which fine-tunes the weights w_{mj} one by one to decrease impurity. CART also has a preprocessing stage to decrease dimensionality through subset selection (chapter 6) and reduce the complexity of the node. An algorithm with some extensions

OC1 to CART is the *OC1* algorithm (Murthy, Kasif, and Salzberg 1994). One possibility (Loh and Vanichsetakul 1988) is to assume that all classes are Gaussian with a common covariance matrix, thereby having linear discriminants separating each class from the others (chapter 5). In such a case, with K classes, each node has K branches and each branch carries the discriminant separating one class from the others. Brodley and Utgoff (1995) propose a method where the linear discriminants are trained to minimize classification error (chapter 10). Guo and Gelfand (1992) propose a heuristic to group $K > 2$ classes into two supergroups, and then binary multivariate trees can be learned. Loh and Shih (1997) use 2-means clustering (chapter 7) to group data into two. Yıldız and Alpaydın (2000) use LDA (chapter 6) to find the discriminant once the classes are grouped into two.

Any classifier approximates the real (unknown) discriminant choosing one hypothesis from its hypothesis class. When we use univariate nodes, our approximation uses piecewise, axis-aligned hyperplanes. With linear multivariate nodes, we can use arbitrary hyperplanes and do a better approximation using fewer nodes. If the underlying discriminant is curved, nonlinear nodes work better. The branching factor has a similar effect in that it specifies the number of discriminants that a node defines. A binary decision node with two branches defines one discriminant separating the input space into two. An n-way node separates into n. Thus, there is a dependency among the complexity of a node, the branching factor, and tree size. With simple nodes and low branching factors, one may grow large trees, but on the other hand, such trees, for example, with univariate binary nodes, are more interpretable. Linear multivariate nodes are more difficult to interpret. More complex nodes also require more data and are prone to overfitting as we get down the tree and have less and less data. If the nodes are complex and the tree is small, we also lose the main idea of the tree, which is that of dividing the problem into a set of simple problems. After all, we can have a very complex classifier in the root that separates all classes from each other, but then this will not be a tree!

9.7 Notes

Divide-and-conquer is a frequently used heuristic that has been used since the days of Caesar to break a complex problem, for example, Gaul,

into a group of simpler problems. Trees are frequently used in computer science to decrease complexity from linear to log time. Decision trees were made popular in statistics in Breiman et al. 1984 and in machine learning in Quinlan 1986, 1993. Multivariate tree induction methods became popular more recently; a review and comparison on many datasets are given in Yıldız and Alpaydın 2000. Many researchers (e.g., Guo and Gelfand 1992), proposed to combine the simplicity of trees with the accuracy of multilayer perceptrons (chapter 11). Many studies, however, have concluded that the univariate trees are quite accurate and interpretable, and the additional complexity brought by linear (or nonlinear) multivariate nodes is hardly justified.

OMNIVARIATE DECISION TREE

The *omnivariate decision tree* (Yıldız and Alpaydın 2001) is a hybrid tree architecture where the tree may have univariate, linear multivariate, or nonlinear multivariate nodes. The idea is that during construction, at each decision node, which corresponds to a different subproblem defined by the subset of the training data reaching that node, a different model may be appropriate and the appropriate one should be found and used. Using the same type of nodes everywhere corresponds to assuming that the same inductive bias is good in all parts of the input space. In an omnivariate tree, at each node, candidate nodes of different types are trained and compared using a statistical test (chapter 14) on a validation set to determine which one generalizes the best. The simpler one is chosen unless a more complex one is shown to have significantly higher accuracy. Results show that more complex nodes are used early in the tree, closer to the root, and as we go down the tree, simple univariate nodes suffice. As we get closer to the leaves, we have simpler problems and, at the same time, we have less data. In such a case, complex nodes overfit and are rejected by the statistical test. The number of nodes increases exponentially as we go down the tree; therefore, a large majority of the nodes are univariate and the overall complexity does not increase much.

Decision trees are used more frequently for classification than for regression. They are very popular: They learn and respond quickly, and are accurate in many domains (Murthy 1998). It is even the case that a decision tree is preferred over more accurate methods, because it is interpretable. When written down as a set of IF-THEN rules, the tree can be understood and the rules can be validated by human experts who have knowledge of the application domain.

It is generally recommended that a decision tree be tested and its accuracy be taken as a benchmark before more complicated algorithms are

employed. Analysis of the tree also allows an understanding of the important features, and the univariate tree does its own automatic feature extraction. Another big advantage of the univariate tree is that it can use numeric and discrete features together, without needing to convert one type into the other.

The decision tree is a nonparametric method, similar to the methods discussed in chapter 8, but there are a number of differences:

- Each leaf node corresponds to a "bin," except that the bins need not be the same size (as in Parzen windows) or contain an equal number of training instances (as in k-nearest neighbor).

- The bin divisions are not done based only on similarity in the input space, but the required output information through entropy or mean square error is also used.

- Another advantage of the decision tree is that the leaf ("bin") is found much faster with smaller number of comparisons.

- The decision tree, once it is constructed, does not store all the training set but only the structure of the tree, the parameters of the decision nodes, and the output values in leaves; this implies that the space complexity is also much less, as opposed to kernel- or neighbor-based nonparametric methods, which need to store all of the training examples.

With a decision tree, a class need not have a single description to which all instances should match. It may have a number of possible descriptions that can even be disjoint in the input space.

The tree is different from the statistical models discussed in previous chapters. The tree codes directly the discriminants separating class instances without caring much for how those instances are distributed in the regions. The decision tree is *discriminant-based,* whereas the statistical methods are *likelihood-based* in that they explicitly estimate $p(\mathbf{x}|C_i)$ before using Bayes' rule and calculating the discriminant. Discriminant-based methods directly estimate the discriminants, bypassing the estimation of class densities. We further discuss discriminant-based methods in the chapters ahead.

9.8 Exercises

1. Generalize the Gini index (equation 9.5) and the misclassification error (equation 9.6) for $K > 2$ classes. Generalize misclassification error to risk, taking a loss function into account.

2. For a numeric input, instead of a binary split, one can use a ternary split with two thresholds and three branches as

   $$x_j < w_{ma},\ w_{ma} \leq x_j < w_{mb},\ x_j \geq w_{mb}$$

   Propose a modification of the tree induction method to learn the two thresholds, w_{ma}, w_{mb}. What are the advantages and the disadvantages of such a node over a binary node?

3. Propose a tree induction algorithm with backtracking.

4. In generating a univariate tree, a discrete attribute with n possible values can be represented by n 0/1 dummy variables and then treated as n separate numeric attributes. What are the advantages and disadvantages of this approach?

5. Derive a learning algorithm for sphere trees (equation 9.21). Generalize to ellipsoid trees.

6. In a regression tree, we discussed that in a leaf node, instead of calculating the mean, we can do a linear regression fit and make the response at the leaf dependent on the input. Propose a similar method for classification trees.

7. Propose a rule induction algorithm for regression.

10 Linear Discrimination

In linear discrimination, we assume that instances of a class are linearly separable from instances of other classes. This is a discriminant-based approach that estimates the parameters of the discriminant directly, without first estimating probabilities. In this chapter, we see different learning algorithms with different inductive biases for learning such linear discriminants from a given labeled training sample.

10.1 Introduction

WE REMEMBER from the previous chapters that in classification we define a set of discriminant functions $g_j(\boldsymbol{x}), j = 1, \ldots, K$, and then we

$$\text{choose } C_i \text{ if } g_i(\boldsymbol{x}) = \max_{j=1}^{K} g_j(\boldsymbol{x})$$

Previously, when we discussed methods for classification, we first estimated the prior probabilities, $\hat{P}(C_i)$, and the class likelihoods, $\hat{p}(\boldsymbol{x}|C_i)$, then used Bayes' rule to calculate the posterior densities. We then defined the discriminant functions in terms of the posterior, for example,

$$g_i(\boldsymbol{x}) = \log \hat{P}(C_i|\boldsymbol{x})$$

LIKELIHOOD-BASED CLASSIFICATION

This is called *likelihood-based classification,* and we have previously discussed the parametric (chapter 5), semiparametric (chapter 7), and nonparametric (chapter 8) approaches to estimating the class likelihoods, $p(\boldsymbol{x}|C_i)$.

DISCRIMINANT-BASED CLASSIFICATION

We are now going to discuss *discriminant-based classification* where we assume a model directly for the discriminant, bypassing the estimation of

likelihoods or posteriors. The discriminant-based approach makes an assumption on the form of the discriminant between the classes and makes no assumption about, or requires no knowledge of the densities, for example, whether they are Gaussian, or whether the inputs are correlated, and so forth. The discriminant-based approach is said to be *nonparametric*, parameters in this sense referring to the parameters of the class-likelihood densities.

We define a model for the discriminant

$$g_i(\mathbf{x}|\Phi_i)$$

explicitly parameterized with the set of parameters Φ_i, as opposed to a likelihood-based scheme that has implicit parameters in defining the likelihood densities. This is a different inductive bias: Instead of making an assumption on the form of the densities, we make an assumption on the form of the discriminants.

Learning is the optimization of the model parameters Φ_i to maximize the classification accuracy on a given labeled training set. This differs from the likelihood-based methods that search for the parameters that maximize sample likelihoods, separately for each class.

In the discriminant-based approach, we do not care about correctly estimating the densities inside class regions; all we care about is the correct estimation of the *boundaries* between the class regions. Those who advocate the discriminant-based approach (e.g., Cherkassky and Mulier 1998) state that estimating the class densities is a harder problem than estimating the class discriminants, and it does not make sense to solve a hard problem to solve an easier problem. This is of course true only when the discriminant can be approximated by a simple function.

In this chapter, we concern ourselves with the simplest case where the discriminant functions are linear in $\mathbf{x}$:

$$g_i(\mathbf{x}|\mathbf{w}_i, w_{i0}) = \mathbf{w}_i^T\mathbf{x} + w_{i0} = \sum_{j=1}^{d} w_{ij}x_j + w_{i0} \tag{10.1}$$

LINEAR DISCRIMINANT

The *linear discriminant* is used frequently mainly due to its simplicity, namely, both the space and time complexities are $\mathcal{O}(d)$. The linear model is easy to understand: The final output is a weighted sum of several factors. The magnitute of the weights show the importance of these factors and their sign show if the effect is positive or negative. Most functions are additive in that the output is the sum of the effects of several attributes where the weights may be positive (enforcing) or negative (inhibiting). For

example, when a customer applies for credit, financial institutions calculate the applicant's credit score which is generally written as a sum of the effects of various attributes; for example, yearly income has a positive effect (higher incomes increase the score).

In many applications, the linear discriminant is also quite accurate. We know, for example, that when classes are Gaussian with a shared covariance matrix, the optimal discriminant is linear. The linear discriminant, however, can be used even when this assumption does not hold and the model parameters can be calculated without making any assumptions on the class densities. We should always use the linear discriminant before trying a more complicated model to make sure that the additional complexity is justified.

As always, we formulate the problem of finding a linear discriminant function as a search for the parameter values that minimize an error function. In particular, we concentrate on *gradient* methods for optimizing a criterion function.

10.2 Generalizing the Linear Model

When a linear model is not flexible enough, we can increase complexity and write the *quadratic discriminant* function

QUADRATIC DISCRIMINANT

$$g_i(\mathbf{x}|\mathbf{W}_i, \mathbf{w}_i, w_{i0}) = \mathbf{x}^T\mathbf{W}_i\mathbf{x} + \mathbf{w}_i\mathbf{x} + w_{i0} \tag{10.2}$$

but this approach is $O(d^2)$ and we again have the bias/variance dilemma: The quadratic model, though is more general, requires much larger training sets, and may overfit on small samples.

HIGHER-ORDER TERMS
PRODUCT TERMS

An equivalent way is to preprocess the input by adding *higher-order terms*, also called *product terms*. For example, with two inputs x_1 and x_2, we can define new variables

$$z_1 = x_1, z_2 = x_2, z_3 = x_1^2, z_4 = x_2^2, z_5 = x_1x_2$$

and take $\mathbf{z} = [z_1, z_2, z_3, z_4, z_5]^T$ as the input. The linear function defined in the five-dimensional $\mathbf{z}$ space corresponds to a nonlinear function in the two-dimensional $\mathbf{x}$ space. Instead of defining a nonlinear function (discriminant or regression) in the original space, what we do is to define a suitable nonlinear transformation to a new space where the function can be written in a linear form.

We write the discriminant as

$$g_i(\mathbf{x}) = \sum_{j=1}^{k} w_j \phi_{ij}(\mathbf{x}) \tag{10.3}$$

BASIS FUNCTION

where $\phi_{ij}(\mathbf{x})$ are *basis functions.* Examples are

- $\sin(x_1)$
- $\exp(-(x_1 - m)^2/c)$
- $\exp(-\|\mathbf{x} - \mathbf{m}\|^2/c)$
- $\log(x_2)$
- $1(x_1 > c)$
- $1(ax_1 + bx_2 > c)$

where m, a, b, c are scalars, $\mathbf{m}$ is a d-dimensional vector, and $1(b)$ returns 1 if b is true and returns 0 otherwise. The idea of writing a nonlinear function as a linear sum of nonlinear basis functions is an old idea and

POTENTIAL FUNCTION

was originally called *potential functions* (Aizerman, Braverman, and Rozonoer 1964). In section 10.9, we discuss support vector machines that use such basis functions. Multilayer perceptrons (chapter 11) and radial basis functions (chapter 12) have the further advantage that the parameters of the basis functions can be fine-tuned to the data during learning.

10.3 Geometry of the Linear Discriminant

10.3.1 Two Classes

Let us start with the simpler case of two classes. In such a case, one discriminant function is sufficient:

$$\begin{aligned} g(\mathbf{x}) &= g_1(\mathbf{x}) - g_2(\mathbf{x}) \\ &= (\mathbf{w}_1^T\mathbf{x} + w_{10}) - (\mathbf{w}_2^T\mathbf{x} + w_{20}) \\ &= (\mathbf{w}_1 - \mathbf{w}_2)^T\mathbf{x} + (w_{10} - w_{20}) \\ &= \mathbf{w}^T\mathbf{x} + w_0 \end{aligned}$$

and we

$$\text{choose} \begin{cases} C_1 & \text{if } g(\mathbf{x}) > 0 \\ C_2 & \text{otherwise} \end{cases}$$

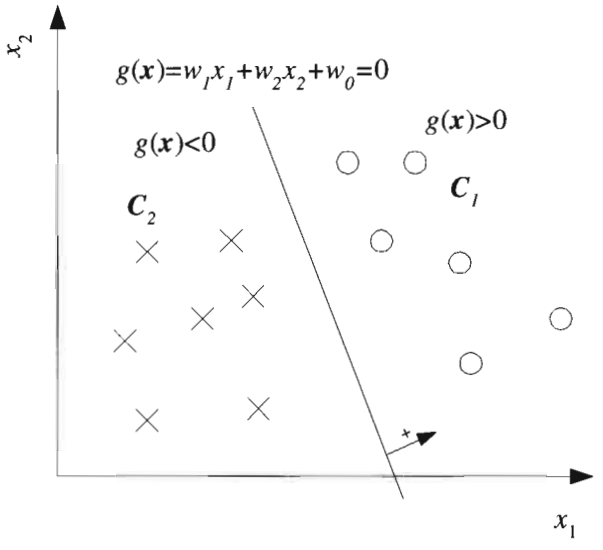

Figure 10.1 In the two-dimensional case, the linear discriminant is a line that separates the examples from two classes.

WEIGHT VECTOR
THRESHOLD

This defines a hyperplane where $\boldsymbol{w}$ is the *weight vector* and w_0 is the *threshold.* This latter name comes from the fact that the decision rule can be rewritten as follows: Choose C_1 if $\boldsymbol{w}^T\boldsymbol{x} > -w_0$, and choose C_2 otherwise. The hyperplane divides the input space into two half-spaces: The decision region $\mathcal{R}_1$ for C_1 and $\mathcal{R}_2$ for C_2. Any $\boldsymbol{x}$ in $\mathcal{R}_1$ is on the *positive* side of the hyperplane and any $\boldsymbol{x}$ in $\mathcal{R}_2$ is on its *negative* side. When $\boldsymbol{x}$ is $\mathbf{0}$, $g(\boldsymbol{x}) = w_0$ and we see that if $w_0 > 0$, the origin is on the positive side of the hyperplane and if $w_0 < 0$, the origin is on the negative side and if $w_0 = 0$, the hyperplane passes through the origin (see figure 10.1).

Take two points $\boldsymbol{x}_1$ and $\boldsymbol{x}_2$ both on the decision surface, that is, $g(\boldsymbol{x}_1) = g(\boldsymbol{x}_2) = 0$, then

$$\begin{aligned} \boldsymbol{w}^T\boldsymbol{x}_1 + w_0 &= \boldsymbol{w}^T\boldsymbol{x}_2 + w_0 \\ \boldsymbol{w}^T(\boldsymbol{x}_1 - \boldsymbol{x}_2) &= 0 \end{aligned}$$

and we see that $\boldsymbol{w}$ is normal to any vector lying on the hyperplane. Let us rewrite $\boldsymbol{x}$ as (Duda, Hart, and Stork 2001)

$$\boldsymbol{x} = \boldsymbol{x}_p + r\frac{\boldsymbol{w}}{\|\boldsymbol{w}\|}$$

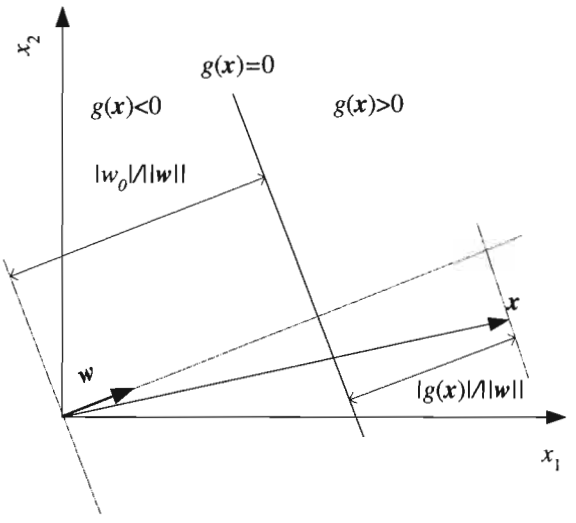

Figure 10.2 The geometric interpretation of the linear discriminant.

where $\mathbf{x}_p$ is the normal projection of $\mathbf{x}$ onto the hyperplane and r gives us the distance from $\mathbf{x}$ to the hyperplane, negative if $\mathbf{x}$ is on the negative side, and positive if $\mathbf{x}$ is on the positive side (see figure 10.2). Calculating $g(\mathbf{x})$ and noting that $g(\mathbf{x}_p) = 0$, we have

$$r = \frac{g(\mathbf{x})}{\|\mathbf{w}\|} \tag{10.4}$$

We see then that the distance to origin is

$$r_0 = \frac{w_0}{\|\mathbf{w}\|} \tag{10.5}$$

Thus w_0 determines the location of the hyperplane with respect to the origin, and $\mathbf{w}$ determines its orientation.

10.3.2 Multiple Classes

When there are $K > 2$ classes, there are K discriminant functions. When they are linear, we have

$$g_i(\mathbf{x}|\mathbf{w}_i, w_{i0}) = \mathbf{w}_i^T\mathbf{x} + w_{i0} \tag{10.6}$$

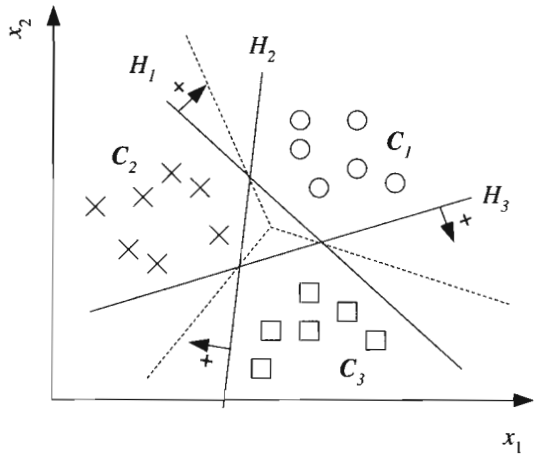

Figure 10.3 In linear classification, each hyperplane H_i separates the examples of C_i from the examples of all other classes. Thus for it to work, the classes should be linearly separable. Dotted lines are the induced boundaries of the linear classifier.

We are going to talk about learning later on but for now, we assume that the parameters, $\boldsymbol{w}_i, w_{i0}$, are computed so as to have

$$g_i(\boldsymbol{x}|\boldsymbol{w}_i, w_{i0}) = \begin{cases} > 0 & \text{if } \boldsymbol{x} \in C_i \\ \leq 0 & \text{otherwise} \end{cases} \tag{10.7}$$

for all $\boldsymbol{x}$ in the training set. Using such discriminant functions corresponds to assuming that all classes are *linearly separable;* that is, for each class C_i, there exists a hyperplane H_i such that on its positive side lie all $\boldsymbol{x} \in C_i$ and on its negative side lie all $\boldsymbol{x} \in C_j, j \neq i$ (see figure 10.3).

LINEARLY SEPARABLE CLASSES

During testing, given $\boldsymbol{x}$, ideally, we should have only one $g_j(\boldsymbol{x}), j = 1, \ldots, K$ greater than 0 and all others should be less than 0, but this is not always the case: The positive half-spaces of the hyperplanes may overlap, or, we may have a case where all $g_j(\boldsymbol{x}) < 0$. These may be taken as *reject* cases, but the usual approach is to assign $\boldsymbol{x}$ to the class having the highest discriminant:

$$\text{Choose } C_i \text{ if } g_i(\boldsymbol{x}) = \max_{j=1}^{K} g_j(\boldsymbol{x}) \tag{10.8}$$

Remembering that $|g_i(\boldsymbol{x})|/\|\boldsymbol{w}_i\|$ is the distance from the input point to the hyperplane, assuming that all $\boldsymbol{w}_i$ have similar length, this assigns the

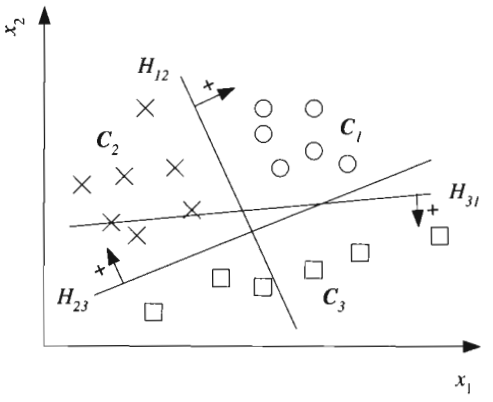

Figure 10.4 In pairwise linear separation, there is a separate hyperplane for each pair of classes. For an input to be assigned to C_1, it should be on the positive side of H_{12} and H_{13} (which is the negative side of H_{31}); we do not care for the value of H_{23}. In this case, C_1 is not linearly separable from other classes but is pairwise linearly separable.

LINEAR CLASSIFIER

point to the class (among all $g_j(\boldsymbol{x}) > 0$) to whose hyperplane the point is most distant. This is called a *linear classifier* and geometrically, it divides the feature space into K convex decision regions $\mathcal{R}_i$ (see figure 10.3).

10.4 Pairwise Separation

PAIRWISE SEPARATION

If the classes are not linearly separable, one approach is to divide it into a set of linear problems. One possibility is *pairwise separation* of classes (Duda, Hart, and Stork 2001). It uses $K(K-1)/2$ linear discriminants, $g_{ij}(\boldsymbol{x})$, one for every pair of distinct classes (see figure 10.4):

$$g_{ij}(\boldsymbol{x}|\boldsymbol{w}_{ij}, w_{ij0}) = \boldsymbol{w}_{ij}^T\boldsymbol{x} + w_{ij0}$$

The parameters $\boldsymbol{w}_{ij}, j \neq i$ are computed during training so as to have

$$g_{ij}(\boldsymbol{x}) = \begin{cases} > 0 & \text{if } \boldsymbol{x} \in C_i \\ \leq 0 & \text{if } \boldsymbol{x} \in C_j \\ \text{don't care} & \text{otherwise} \end{cases} \quad i, j = 1, \ldots, K \text{ and } i \neq j \tag{10.9}$$

that is, if $\boldsymbol{x}^t \in C_k$ where $k \neq i, k \neq j$, then $\boldsymbol{x}^t$ is not used during training of $g_{ij}(\boldsymbol{x})$.

During testing, we

choose C_i if $\forall j \neq i, g_{ij}(\boldsymbol{x}) > 0$

In many cases, this may not be true for any i and if we do not want to reject such cases, we can relax the conjunction by using a summation

$$g_i(\boldsymbol{x}) = \sum_{j \neq i} g_{ij}(\boldsymbol{x}) \tag{10.10}$$

Even if the classes are not linearly separable, if the classes are pairwise linearly separable, which is much more likely, then pairwise separation can be used, leading to nonlinear separation of classes (see figure 10.4). This is another example of breaking down a complex, for example, nonlinear, problem, into a set of simpler, for example, linear, problems. We have already seen decision trees (chapter 9) that use this idea, and we will see more examples of this in chapter 15 on combining multiple models, for example, error-correcting output codes, and mixture of experts, where the number of linear models is less than $\mathcal{O}(K^2)$.

10.5 Parametric Discrimination Revisited

In chapter 5, we saw that if the class densities, $p(\boldsymbol{x}|C_i)$, are Gaussian and share a common covariance matrix, the discriminant function is linear

$$g_i(\boldsymbol{x}) = \boldsymbol{w}_i^T \boldsymbol{x} + w_{i0} \tag{10.11}$$

where the parameters can be analytically calculated as

$$\begin{aligned} \boldsymbol{w}_i &= \boldsymbol{\Sigma}^{-1}\boldsymbol{\mu}_i \\ w_{i0} &= -\frac{1}{2}\boldsymbol{\mu}_i^T\boldsymbol{\Sigma}^{-1}\boldsymbol{\mu}_i + \log P(C_i) \end{aligned} \tag{10.12}$$

Given a dataset, we first calculate the estimates for $\boldsymbol{\mu}_i$ and $\boldsymbol{\Sigma}$ and then plug the estimates, $\boldsymbol{m}_i$, $\mathbf{S}$, in equation 10.12 and calculate the parameters of the linear discriminant.

Let us again see the special case where there are two classes: We define $y \equiv P(C_1|\boldsymbol{x})$ and $p(C_2|\boldsymbol{x}) = 1 - y$. Then in classification, we

$$\text{choose } C_1 \text{ if } \begin{cases} y > 0.5 \\ \frac{y}{1-y} > 1 \\ \log \frac{y}{1-y} > 0 \end{cases} \quad \text{and } C_2 \text{ otherwise}$$

LOGIT
LOG ODDS

$\log y/(1-y)$ is known as the *logit* transformation or *log odds* of y. In

the case of two normal classes sharing a common covariance matrix, the log odds is linear:

$$\begin{aligned}\text{logit}(P(C_1|\boldsymbol{x})) &= \log\frac{P(C_1|\boldsymbol{x})}{1-P(C_1|\boldsymbol{x})} = \log\frac{P(C_1|\boldsymbol{x})}{P(C_2|\boldsymbol{x})}\\ &= \log\frac{p(\boldsymbol{x}|C_1)}{p(\boldsymbol{x}|C_2)} + \log\frac{P(C_1)}{P(C_2)}\\ &= \log\frac{(2\pi)^{-d/2}|\boldsymbol{\Sigma}|^{-1/2}\exp[-(1/2)(\boldsymbol{x}-\boldsymbol{\mu}_1)^T\boldsymbol{\Sigma}^{-1}(\boldsymbol{x}-\boldsymbol{\mu}_1)]}{(2\pi)^{-d/2}|\boldsymbol{\Sigma}|^{-1/2}\exp[-(1/2)(\boldsymbol{x}-\boldsymbol{\mu}_2)^T\boldsymbol{\Sigma}^{-1}(\boldsymbol{x}-\boldsymbol{\mu}_2)]} + \log\frac{P(C_1)}{P(C_2)}\\ &= \boldsymbol{w}^T\boldsymbol{x} + w_0 \qquad (10.13)\end{aligned}$$

where

$$\begin{aligned}\boldsymbol{w} &= \boldsymbol{\Sigma}^{-1}(\boldsymbol{\mu}_1-\boldsymbol{\mu}_2)\\ w_0 &= -\frac{1}{2}(\boldsymbol{\mu}_1+\boldsymbol{\mu}_2)^T\boldsymbol{\Sigma}^{-1}(\boldsymbol{\mu}_1-\boldsymbol{\mu}_2) + \log\frac{P(C_1)}{P(C_2)} \qquad (10.14)\end{aligned}$$

The inverse of logit

$$\log\frac{P(C_1|\boldsymbol{x})}{1-P(C_1|\boldsymbol{x})} = \boldsymbol{w}^T\boldsymbol{x} + w_0$$

LOGISTIC SIGMOID

is the *logistic* function, also called the *sigmoid* function (see figure 10.5):

$$P(C_1|\boldsymbol{x}) = \text{sigmoid}(\boldsymbol{w}^T\boldsymbol{x} + w_0) = \frac{1}{1+\exp[-(\boldsymbol{w}^T\boldsymbol{x} + w_0)]} \qquad (10.15)$$

During training, we estimate $\boldsymbol{m}_1, \boldsymbol{m}_2, \mathbf{S}$ and plug these estimates in equation 10.14 to calculate the discriminant parameters. During testing, given $\boldsymbol{x}$, we can either

1. calculate $g(\boldsymbol{x}) = \boldsymbol{w}^T\boldsymbol{x} + w_0$ and choose C_1 if $g(\boldsymbol{x}) > 0$, or
2. calculate $y = \text{sigmoid}(\boldsymbol{w}^T\boldsymbol{x} + w_0)$ and choose C_1 if $y > 0.5$,

because $\text{sigmoid}(0) = 0.5$. In this latter case, sigmoid transforms the discriminant value to a posterior probability. This is valid when there are two classes and one discriminant; we see in section 10.7 how we can estimate posterior probabilities for $K > 2$.

10.6 Gradient Descent

In likelihood-based classification, the parameters were the sufficient statistics of $p(\boldsymbol{x}|C_i)$ and $P(C_i)$ and the method we used to estimate the parameters is maximum likelihood. In the discriminant-based approach, the

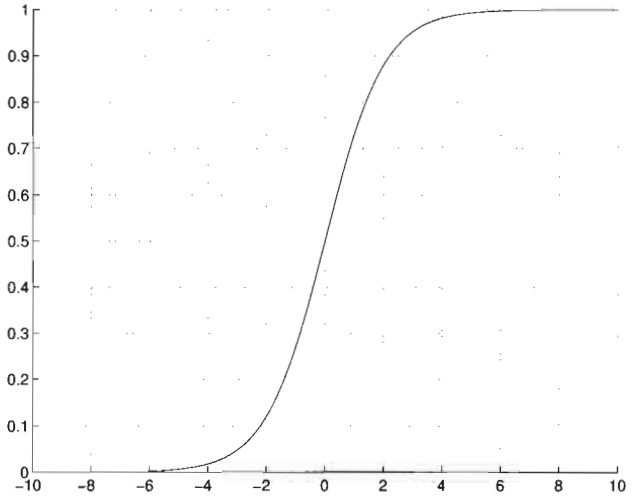

Figure 10.5 The logistic, or sigmoid, function.

parameters are those of the discriminants, and they are optimized to minimize the classification error on the training set. When $\mathbf{w}$ denotes the set of parameters and $E(\mathbf{w}|\mathcal{X})$ is the error with parameters $\mathbf{w}$ on the given training set $\mathcal{X}$, we look for

$$\mathbf{w}^* = \arg\min_{\mathbf{w}} E(\mathbf{w}|\mathcal{X})$$

In many cases, some of which we will see shortly, there is no analytical solution and we need to resort to iterative optimization methods; the most commonly employed is that of *gradient descent:* When $E(\mathbf{w})$ is a differentiable function of a vector of variables, we have the *gradient vector* composed of the partial derivatives

GRADIENT DESCENT
GRADIENT VECTOR

$$\nabla_w E = \left[\frac{\partial E}{\partial w_1}, \frac{\partial E}{\partial w_2}, \ldots, \frac{\partial E}{\partial w_d}\right]^T$$

and the *gradient descent* procedure to minimize E, starts from a random $\mathbf{w}$, and at each step, updates $\mathbf{w}$, in the opposite direction of the gradient

$$\Delta w_i = -\eta \frac{\partial E}{\partial w_i}, \forall i \tag{10.16}$$

$$w_i = w_i + \Delta w_i \tag{10.17}$$

where η is called the *stepsize,* or *learning factor* and determines how much to move in that direction. Gradient-ascent is used to maximize a

function and goes in the direction of the gradient. When we get to a minimum (or maximum), the derivative is 0 and the procedure terminates. This indicates that the procedure finds the nearest minimum that can be a local minimum, and there is no guarantee of finding the global minimum unless the function has only one minimum. The use of a good value for η is also critical; if it is too small, the convergence may be too slow, and a large value may cause oscillations and even divergence.

Throughout this book, we use gradient methods that are simple and quite effective. We keep in mind, however, that once a suitable model and an error function is defined, the optimization of the model parameters to minimize the error function can be done by using one of many possible techniques. There are second-order methods and conjugate-gradient that converge faster, at the expense of more memory and computation. More costly methods like simulated annealing and genetic algorithms allow a more thorough search of the parameter space and do not depend as much on the initial point.

10.7 Logistic Discrimination

10.7.1 Two Classes

LOGISTIC DISCRIMINATION

In *logistic discrimination*, we do not model the class-conditional densities, $p(\boldsymbol{x}|C_i)$, but rather their ratio. Let us again start with two classes and assume that the log likelihood ratio is linear:

$$\log \frac{p(\boldsymbol{x}|C_1)}{p(\boldsymbol{x}|C_2)} = \boldsymbol{w}^T\boldsymbol{x} + w_0^o \tag{10.18}$$

This indeed holds when the class-conditional densities are normal (equation 10.13). But logistic discrimination has a wider scope of applicability; for example, $\boldsymbol{x}$ may be composed of discrete attributes or may be a mixture of continuous and discrete attributes.

Using Bayes' rule, we have

$$\begin{aligned} \text{logit}(P(C_1|\boldsymbol{x})) &= \log \frac{P(C_1|\boldsymbol{x})}{1 - P(C_1|\boldsymbol{x})} \\ &= \log \frac{p(\boldsymbol{x}|C_1)}{p(\boldsymbol{x}|C_2)} + \log \frac{P(C_1)}{P(C_2)} \\ &= \boldsymbol{w}^T\boldsymbol{x} + w_0 \end{aligned} \tag{10.19}$$

where

$$w_0 = w_0^o + \log \frac{P(C_1)}{P(C_2)} \tag{10.20}$$

Rearranging terms, we get the sigmoid function again:

$$y = \hat{P}(C_1|\boldsymbol{x}) = \frac{1}{1 + \exp[-(\boldsymbol{w}^T\boldsymbol{x} + w_0)]} \tag{10.21}$$

as our estimator of $P(C_1|\boldsymbol{x})$.

Let us see how we can learn $\boldsymbol{w}$ and w_0: We are given a sample of two classes, $\mathcal{X} = \{\boldsymbol{x}^t, r^t\}$, where $r^t = 1$ if $\boldsymbol{x} \in C_1$ and $r^t = 0$ if $\boldsymbol{x} \in C_2$. We assume r^t, given $\boldsymbol{x}^t$, is Bernoulli with probability $y^t \equiv P(C_1|\boldsymbol{x}^t)$ as calculated in equation 10.21:

$$r^t|\boldsymbol{x}^t \sim \text{Bernoulli}(y^t)$$

Here, we see the difference from the likelihood-based methods where we modeled $p(\boldsymbol{x}|C_i)$; in the discriminant-based approach, we model directly $r|\boldsymbol{x}$. The sample likelihood is

$$l(\boldsymbol{w}, w_0|\mathcal{X}) = \prod_t (y^t)^{(r^t)}(1 - y^t)^{(1-r^t)} \tag{10.22}$$

We know that when we have a likelihood function to maximize, we can always turn it into an error function to be minimized as $E = -\log l$, and in our case, we have *cross-entropy:*

CROSS-ENTROPY

$$E(\boldsymbol{w}, w_o|\mathcal{X}) = -\sum_t r^t \log y^t + (1 - r^t)\log(1 - y^t) \tag{10.23}$$

We use gradient-descent to minimize cross-entropy, equivalent to maximizing the likelihood or the log likelihood. If $y = \text{sigmoid}(a) = 1/(1 + \exp(-a))$, its derivative is given as

$$\frac{dy}{da} = y(1 - y)$$

and we get the following update equations:

$$\begin{aligned} \Delta w_j &= -\eta \frac{\partial E}{\partial w_j} = \eta \sum_t \left(\frac{r^t}{y^t} - \frac{1 - r^t}{1 - y^t} \right) y^t(1 - y^t)x_j^t \\ &= \eta \sum_t (r^t - y^t)x_j^t, j = 1, \ldots, d \\ \Delta w_0 &= -\eta \frac{\partial E}{\partial w_0} = \eta \sum_t (r^t - y^t) \end{aligned} \tag{10.24}$$

```
For j = 0,...,d
    w_j ← rand(-0.01,0.01)
Repeat
    For j = 0,...,d
        Δw_j ← 0
    For t = 1,...,N
        o ← 0
        For j = 0,...,d
            o ← o + w_j x_j^t
        y ← sigmoid(o)
        Δw_j ← Δw_j + (r^t − y) x_j^t
    For j = 0,...,d
        w_j ← w_j + η Δw_j
Until convergence
```

Figure 10.6 Logistic discrimination algorithm implementing gradient-descent for the single output case with two classes. For w_0, we assume that there is an extra input x_0, which is always +1: $x_0^t \equiv +1, \forall t$.

It is best to initialize w_j with random values close to 0; generally they are drawn uniformly from the interval $[-0.01, 0.01]$. The reason for this is that if the initial w_j are large in magnitude, the weighted sum may also be large and may saturate the sigmoid. We see from figure 10.5 that if the initial weights are close to 0, the sum will stay in the middle region where the derivative is nonzero and an update can take place. If the weighted sum is large in magnitude (smaller than -5 or larger than $+5$), the derivative of the sigmoid will be almost 0 and weights will not be updated.

Pseudocode is given in figure 10.6. We see an example in figure 10.7 where the input is one-dimensional. Both the line $wx + w_0$ and its value after the sigmoid are shown as a function of learning iterations. We see that to get outputs of 0 and 1, the sigmoid hardens, which is achieved by increasing the magnitude of $\mathbf{w}$.

Once training is complete and we have the final $\mathbf{w}$ and w_0, during testing, given $\mathbf{x}$, we calculate $y = \text{sigmoid}(\mathbf{w}^T\mathbf{x} + w_0)$ and we choose C_1 if $y > 0.5$ and choose C_2 otherwise. This implies that to minimize the number of misclassifications, we do not need to continue learning until y are 0 or 1, but only until y is less than or greater than 0.5. If we continue

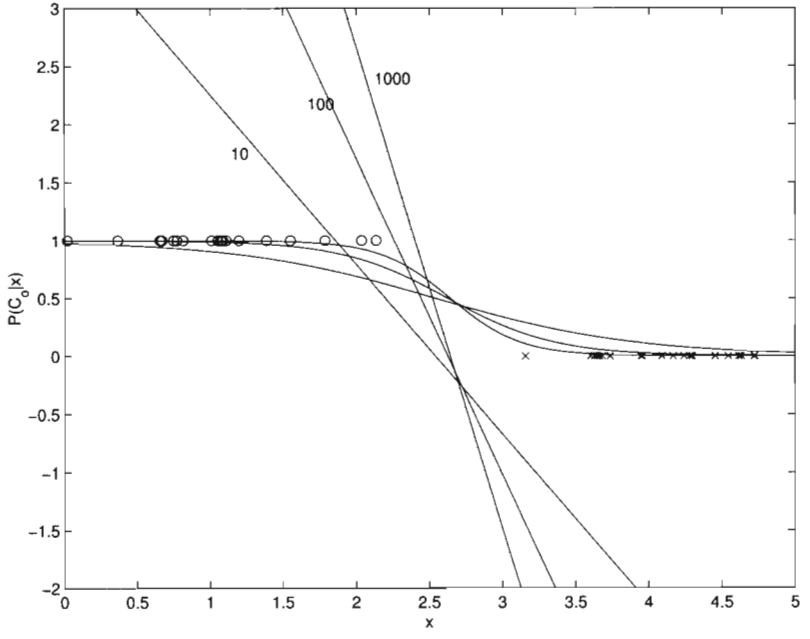

Figure 10.7 For a univariate two-class problem (shown with '$\circ$' and '$\times$'), the evolution of the line $wx + w_0$ and the sigmoid output after 10, 100, and 1,000 iterations over the sample.

training beyond this point, cross-entropy will continue decreasing ($|w_j|$ will continue increasing to harden the sigmoid), but the number of misclassifications will not decrease. Generally, we continue training until the number of misclassifications does not decrease (which will be 0 if the classes are linearly separable).

Note that though we assumed the log ratio of the class densities are linear to derive the discriminant, we estimate directly the posterior and never explicitly estimate $p(\mathbf{x}|C_i)$ or $P(C_i)$.

10.7.2 Multiple Classes

Let us now generalize to $K > 2$ classes: We take one of the classes, for example, C_K, as the reference class and assume that

$$\log \frac{p(\mathbf{x}|C_i)}{p(\mathbf{x}|C_K)} = \mathbf{w}_i^T \mathbf{x} + w_{i0}^o \tag{10.25}$$

Then we have

$$\frac{P(C_i|\mathbf{x})}{P(C_K|\mathbf{x})} = \exp[\mathbf{w}_i^T\mathbf{x} + w_{i0}] \tag{10.26}$$

with $w_{i0} = w_{i0}^o + \log P(C_i)/P(C_K)$.

We see that

$$\sum_{i=1}^{K-1} \frac{P(C_i|\mathbf{x})}{P(C_K|\mathbf{x})} = \frac{1 - P(C_K|\mathbf{x})}{P(C_K|\mathbf{x})} = \sum_{i=1}^{K-1} \exp[\mathbf{w}_i^T\mathbf{x} + w_{i0}]$$

$$\Rightarrow \quad P(C_K|\mathbf{x}) = \frac{1}{1 + \sum_{i=1}^{K-1} \exp[\mathbf{w}_i^T\mathbf{x} + w_{i0}]} \tag{10.27}$$

and also that

$$\frac{P(C_i|\mathbf{x})}{P(C_K|\mathbf{x})} = \exp[\mathbf{w}_i^T\mathbf{x} + w_{i0}]$$

$$\Rightarrow \quad P(C_i|\mathbf{x}) = \frac{\exp[\mathbf{w}_i^T\mathbf{x} + w_{i0}]}{1 + \sum_{j=1}^{K-1} \exp[\mathbf{w}_j^T\mathbf{x} + w_{j0}]}, \quad i = 1, \ldots, K-1 \tag{10.28}$$

To treat all classes uniformly, we can write

$$y_i = \hat{P}(C_i|\mathbf{x}) = \frac{\exp[\mathbf{w}_i^T\mathbf{x} + w_{i0}]}{\sum_{j=1}^{K} \exp[\mathbf{w}_j^T\mathbf{x} + w_{j0}]}, \quad i = 1, \ldots, K \tag{10.29}$$

SOFTMAX which is called the *softmax* function (Bridle 1990). If the weighted sum for one class is sufficiently larger than for the others, after it is boosted through exponentiation and normalization, its corresponding y_i will be close to 1 and the others will be close to 0. Thus it works like taking a maximum, except that it is differentiable; hence the name softmax. Softmax also guarantees that $\sum_i y_i = 1$.

Let us see how we can learn the parameters: In this case of $K > 2$ classes, each sample point is a multinomial trial with one draw, that is, $\mathbf{r}^t|\mathbf{x}^t \sim \text{Mult}_k(1, \mathbf{y}^t)$, where $y_i^t \equiv P(C_i|\mathbf{x}^t)$. The sample likelihood is

$$l(\{\mathbf{w}_i, w_{i0}\}_i|\mathcal{X}) = \prod_t \prod_i (y_i^t)^{r_i^t} \tag{10.30}$$

and the error function is again cross-entropy:

$$E(\{\mathbf{w}_i, w_{i0}\}_i|\mathcal{X}) = -\sum_t \sum_i r_i^t \log y_i^t \tag{10.31}$$

We again use gradient-descent. If $y_i = \exp(a_i)/\sum_j \exp(a_j)$, we have

$$\frac{\partial y_i}{\partial a_j} = y_i(\delta_{ij} - y_j) \tag{10.32}$$

where δ_{ij} is the Kronecker delta, which is 1 if $i = j$ and 0 if $i \neq j$ (exercise 3). Given that $\sum_i r_i^t = 1$, we have the following update equations, for $j = 1, \ldots, K$

$$\begin{aligned}
\Delta \mathbf{w}_j &= \eta \sum_t \sum_i \frac{r_i^t}{y_i^t} y_i^t (\delta_{ij} - y_j^t) \mathbf{x}^t \\
&= \eta \sum_t \sum_i r_i^t (\delta_{ij} - y_j^t) \mathbf{x}^t \\
&= \eta \sum_t \left[\sum_i r_i^t \delta_{ij} - y_j^t \sum_i r_i^t \right] \mathbf{x}^t \\
&= \eta \sum_t (r_j^t - y_j^t) \mathbf{x}^t \\
\Delta w_{j0} &= \eta \sum_t (r_j^t - y_j^t) \qquad (10.33)
\end{aligned}$$

Note that because of the normalization in softmax, $\mathbf{w}_j$ and w_{j0} are affected not only by $\mathbf{x}^t \in C_j$ but also by $\mathbf{x}^t \in C_i, i \neq j$. The discriminants are updated so that the correct class has the highest weighted sum after softmax, and the other classes have their weighted sums as low as possible. Pseudocode is given in figure 10.8. For a two-dimensional example with three classes, the contour plot is given in figure 10.9, and the discriminants and the posterior probabilities in figure 10.10.

During testing, we calculate all $y_k, k = 1, \ldots, K$ and choose C_i if $y_i = \max_k y_k$. Again we do not need to continue training to minimize cross-entropy as much as possible; we train only until the correct class has the highest weighted sum, and therefore we can stop training earlier by checking the number of misclassifications.

When data are normally distributed, the logistic discriminant has comparable error rate to the parametric, normal-based linear discriminant (McLachlan 1992). Logistic discrimination can still be used when the class-conditional densities are nonnormal or when they are not unimodal, as long as classes are linearly separable.

The ratio of class-conditional densities is of course not restricted to be linear (Anderson 1982; McLachlan 1992). Assuming a quadratic discriminant, we have

$$\log \frac{p(\mathbf{x}|C_i)}{p(\mathbf{x}|C_k)} = \mathbf{x}^T \mathbf{W}_i \mathbf{x} + \mathbf{w}_i^T \mathbf{x} + w_{i0} \qquad (10.34)$$

corresponding to and generalizing parametric discrimination with multivariate normal class-conditionals having different covariance matrices.

For $i = 1, \ldots, K$, For $j = 0, \ldots, d$, $w_{ij} \leftarrow \text{rand}(-0.01, 0.01)$
Repeat
  For $i = 1, \ldots, K$, For $j = 0, \ldots, d$, $\Delta w_{ij} \leftarrow 0$
  For $t = 1, \ldots, N$
    For $i = 1, \ldots, K$
      $o_i \leftarrow 0$
      For $j = 0, \ldots, d$
        $o_i \leftarrow o_i + w_{ij} x_j^t$
    For $i = 1, \ldots, K$
      $y_i \leftarrow \exp(o_i) / \sum_k \exp(o_k)$
    For $i = 1, \ldots, K$
      For $j = 0, \ldots, d$
        $\Delta w_{ij} \leftarrow \Delta w_{ij} + (r_i^t - y_i) x_j^t$
  For $i = 1, \ldots, K$
    For $j = 0, \ldots, d$
      $w_{ij} \leftarrow w_{ij} + \eta \Delta w_{ij}$
Until convergence

Figure 10.8 Logistic discrimination algorithm implementing gradient-descent for the case with $K > 2$ classes. For generality, we take $x_0^t \equiv 1, \forall t$.

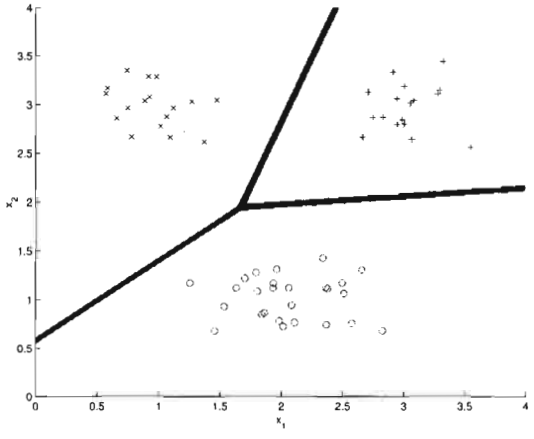

Figure 10.9 For a two-dimensional problem with three classes, the solution found by logistic discrimination. Thin lines are where $g_i(\boldsymbol{x}) = 0$, and the thick line is the boundary induced by the linear classifier choosing the maximum.

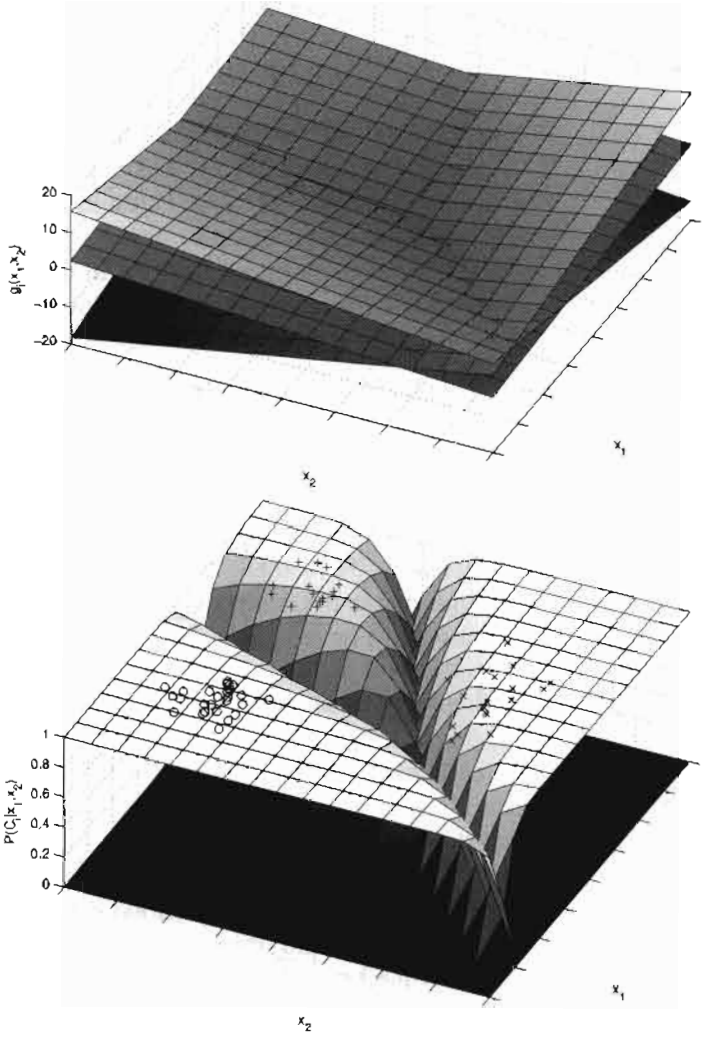

Figure 10.10 For the same example in figure 10.9, the linear discriminants (top), and the posterior probabilities after the softmax (bottom).

When d is large, just as we can simplify (regularize) $\mathbf{\Sigma}_i$, we can equally do it on $\mathbf{W}_i$ by taking only its leading eigenvectors into account.

As discussed in section 10.2, any specified function of the basic variables can be included as x-variates. One can, for example, write the discriminant as a linear sum of nonlinear basis functions

$$\log \frac{p(\mathbf{x}|C_i)}{p(\mathbf{x}|C_k)} = \mathbf{w}_i^T \boldsymbol{\phi}(\mathbf{x}) + w_{i0} \tag{10.35}$$

where $\boldsymbol{\phi}(\cdot)$ are the basis functions, which can be viewed as transformed variables. In neural network terminology, this is called a *multilayer perceptron* (chapter 11) and sigmoid is the most popular basis function. When a Gaussian basis function is used, the model is called *radial basis functions* (chapter 12). We can even use a completely nonparametric approach, for example, Parzen windows (chapter 8).

10.8 Discrimination by Regression

In regression, the probabilistic model is

$$r^t = y^t + \epsilon \tag{10.36}$$

where $\epsilon \sim \mathcal{N}(0, \sigma^2)$. If $r^t \in \{0, 1\}$, y^t can be constrained to lie in this range using the sigmoid function. Assuming a linear model and two classes, we have

$$y^t = \text{sigmoid}(\mathbf{w}^T \mathbf{x}^t + w_0) = \frac{1}{1 + \exp[-(\mathbf{w}^T \mathbf{x}^t + w_0)]} \tag{10.37}$$

Then the sample likelihood in regression, assuming $r|\mathbf{x} \sim \mathcal{N}(y, \sigma^2)$, is

$$l(\mathbf{w}, w_0|\mathcal{X}) = \prod_t \frac{1}{\sqrt{2\pi}\sigma} \exp\left[-\frac{(r^t - y^t)^2}{2\sigma^2}\right] \tag{10.38}$$

Maximizing the log likelihood is minimizing the sum of square errors:

$$E(\mathbf{w}, w_0|\mathcal{X}) = \frac{1}{2}\sum_t (r^t - y^t)^2 \tag{10.39}$$

Using gradient-descent, we get

$$\begin{aligned} \Delta \mathbf{w} &= \eta \sum_t (r^t - y^t) y^t (1 - y^t) \mathbf{x}^t \\ \Delta w_0 &= \eta \sum_t (r^t - y^t) y^t (1 - y^t) \end{aligned} \tag{10.40}$$

This method can also be used when there are $K > 2$ classes. The probabilistic model is

$$\mathbf{r}^t = \mathbf{y}^t + \boldsymbol{\epsilon} \tag{10.41}$$

where $\boldsymbol{\epsilon} \sim \mathcal{N}_K(0, \sigma^2 \mathbf{I}_K)$. Assuming a linear model for each class, we have

$$y_i^t = \text{sigmoid}(\mathbf{w}_i^T \mathbf{x}^t + w_{i0}) = \frac{1}{1 + \exp[-(\mathbf{w}_i^T \mathbf{x}^t + w_{i0})]} \tag{10.42}$$

Then the sample likelihood is

$$l(\{\mathbf{w}_i, w_{i0}\}_i | \mathcal{X}) = \prod_t \frac{1}{(2\pi)^{K/2} |\Sigma|^{1/2}} \exp\left[-\frac{\|\mathbf{r}^t - \mathbf{y}^t\|^2}{2\sigma^2}\right] \tag{10.43}$$

and the error function is

$$E(\{\mathbf{w}_i, w_{i0}\}_i | \mathcal{X}) = \frac{1}{2} \sum_t \|\mathbf{r}^t - \mathbf{y}^t\|^2 = \frac{1}{2} \sum_t \sum_i (r_i^t - y_i^t)^2 \tag{10.44}$$

The update equations for $i = 1, \ldots, K$, are

$$\begin{aligned} \Delta \mathbf{w}_i &= \eta \sum_t (r_i^t - y_i^t) y_i^t (1 - y_i^t) \mathbf{x}^t \\ \Delta w_{i0} &= \eta \sum_t (r_i^t - y_i^t) y_i^t (1 - y_i^t) \end{aligned} \tag{10.45}$$

But note that in doing so, we do not make use of the information that only one of y_i needs to be 1 and all others are 0, or that $\sum_i y_i = 1$. The softmax function of equation 10.29 allows us to incorporate this extra information we have due to the outputs' estimating class posterior probabilities. Using sigmoid outputs in $K > 2$ case, we treat y_i as if they are independent functions.

Note also that for a given class, if we use the regression approach, there will be updates until the right output is 1 and all others are 0. This is not in fact necessary because during testing, we are just going to choose the maximum anyway; it is enough to train only until the right output is larger than others, which is exactly what the softmax function does.

So this approach with multiple sigmoid outputs is more appropriate when the classes are *not* mutually exclusive and exhaustive. That is, for an $\mathbf{x}^t$, all r_i^t may be 0, namely, $\mathbf{x}^t$ does not belong to any of the classes, or more than one r_i^t may be 1, when classes overlap.

10.9 Support Vector Machines

10.9.1 Optimal Separating Hyperplane

We now discuss a different approach to learning the linear discriminant. We should not be surprised to have so many different methods even for the simple case of linear classification. Each method has a different inductive bias, makes different assumptions, and defines a different objective function and thus may find a different linear discriminant.

Let us start again with two classes and use labels $-1/+1$ for the two classes. The sample is $\mathcal{X} = \{\boldsymbol{x}^t, r^t\}$ where $r^t = +1$ if $\boldsymbol{x}^t \in C_1$ and $r^t = -1$ if $\boldsymbol{x}^t \in C_2$. We would like to find $\boldsymbol{w}$ and w_0 such that

$$\begin{aligned} \boldsymbol{w}^T\boldsymbol{x}^t + w_0 &\geq +1 \quad \text{for} \quad r^t = +1 \\ \boldsymbol{w}^T\boldsymbol{x}^t + w_0 &\leq -1 \quad \text{for} \quad r^t = -1 \end{aligned}$$

which can be rewritten as

$$r^t(\boldsymbol{w}^T\boldsymbol{x}^t + w_0) \geq +1 \tag{10.46}$$

Note that we do not simply require

$$r^t(\boldsymbol{w}^T\boldsymbol{x}^t + w_0) \geq 0$$

We do not only want the instances to be on the right side of the hyperplane, but we also want them some distance away, for better generalization. The distance from the hyperplane to the instances closest to it on either side is called the *margin,* which we want to maximize for best generalization. The *optimal separating hyperplane* is the one that maximizes the margin.

MARGIN

OPTIMAL SEPARATING HYPERPLANE

We remember from section 10.3 that the distance of $\boldsymbol{x}^t$ to the discriminant is

$$\frac{|\boldsymbol{w}^T\boldsymbol{x}^t + w_0|}{\|\boldsymbol{w}\|}$$

which, when $r^t \in \{-1, +1\}$, can be written as

$$\frac{r^t(\boldsymbol{w}^T\boldsymbol{x}^t + w_0)}{\|\boldsymbol{w}\|}$$

which we would like to be at least some value ρ.

$$\frac{r^t(\boldsymbol{w}^T\boldsymbol{x}^t + w_0)}{\|\boldsymbol{w}\|} \geq \rho, \forall t \tag{10.47}$$

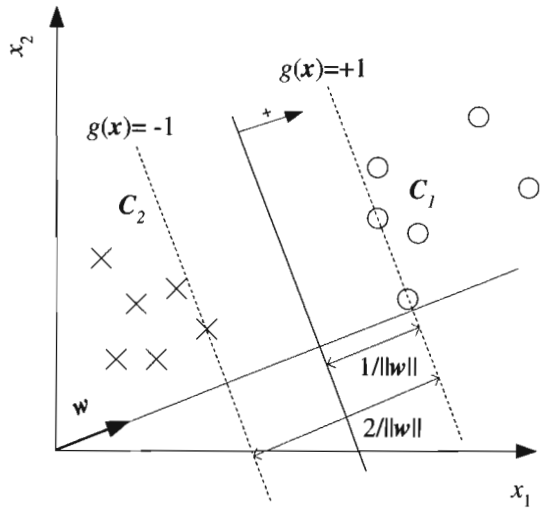

Figure 10.11 On both sides of the optimal separating hyperplance, the instances are at least $1/\|\boldsymbol{w}\|$ away and the total margin is $2/\|\boldsymbol{w}\|$.

We would like to maximize ρ but there are an infinite number of solutions that we can get by scaling $\boldsymbol{w}$ and for a unique solution, we fix $\rho\|\boldsymbol{w}\| = 1$ and thus, to maximize the margin, we minimize $\|\boldsymbol{w}\|$. The task can therefore be defined (see Cortes and Vapnik 1995; Vapnik 1995) as to

$$\min \frac{1}{2}\|\boldsymbol{w}\|^2 \text{ subject to } r^t(\boldsymbol{w}^T\boldsymbol{x}^t + w_0) \geq +1, \forall t \tag{10.48}$$

This is a standard quadratic optimization problem, whose complexity depends on d, and it can be solved directly to find $\boldsymbol{w}$ and w_0. Then, on both sides of the hyperplane, there will be instances that are $1/\|\boldsymbol{w}\|$ away from the hyperplane and the total margin will be $2/\|\boldsymbol{w}\|$ (see figure 10.11).

We saw in section 10.2 that if the problem is not linearly separable, instead of fitting a nonlinear function, one trick we can do is to map the problem to a new space by using nonlinear basis functions. It is generally the case that this new space has many more dimensions than the original space, and in such a case, we are interested in a method whose complexity does not depend on the input dimensionality.

In finding the optimal hyperplane, we can convert the optimization

problem to a form whose complexity depends on N, the number of training instances, and not on d. Another advantage of this new formulation is that it will allow us to rewrite the basis functions in terms of kernel functions, as we see in section 10.9.3.

To get the new formulation, we first write equation 10.48 as an unconstrained problem using Lagrange multipliers α^t:

$$\begin{aligned} L_p &= \frac{1}{2}\|\mathbf{w}\|^2 - \sum_{t=1}^{N} \alpha^t [r^t(\mathbf{w}^T\mathbf{x}^t + w_0) - 1] \\ &= \frac{1}{2}\|\mathbf{w}\|^2 - \sum_t \alpha^t r^t(\mathbf{w}^T\mathbf{x}^t + w_0) + \sum_t \alpha^t \end{aligned} \tag{10.49}$$

This should be minimized with respect to $\mathbf{w}, w_0$ and maximized with respect to $\alpha^t \geq 0$. The saddle point gives the solution.

This is a convex quadratic optimization problem because the main term is convex and the linear constraints are also convex. Therefore, we can equivalently solve the dual problem, making use of the Karush-Kuhn-Tucker conditions. The dual is to *maximize* L_p with respect to α^t, subject to the constraints that the gradient of L_p with respect to $\mathbf{w}$ and w_0 are 0 and also that $\alpha^t \geq 0$:

$$\frac{\partial L_p}{\partial \mathbf{w}} = 0 \quad \Rightarrow \quad \mathbf{w} = \sum_t \alpha^t r^t \mathbf{x}^t \tag{10.50}$$

$$\frac{\partial L_p}{\partial w_0} = 0 \quad \Rightarrow \quad \sum_t \alpha^t r^t = 0 \tag{10.51}$$

Plugging these into equation 10.49, we get the dual

$$\begin{aligned} L_d &= \frac{1}{2}(\mathbf{w}^T\mathbf{w}) - \mathbf{w}^T \sum_t \alpha^t r^t \mathbf{x}^t - w_0 \sum_t \alpha^t r^t + \sum_t \alpha^t \\ &= -\frac{1}{2}(\mathbf{w}^T\mathbf{w}) + \sum_t \alpha^t \\ &= -\frac{1}{2}\sum_t \sum_s \alpha^t \alpha^s r^t r^s (\mathbf{x}^t)^T \mathbf{x}^s + \sum_t \alpha^t \end{aligned} \tag{10.52}$$

which we maximize with respect to α^t only, subject to the constraints

$$\sum_t \alpha^t r^t = 0, \text{ and } \alpha^t \geq 0, \forall t$$

This can be solved using quadratic optimization methods. The size of the dual depends on N, sample size, and not on d, the input dimensionality. The upper bound for time complexity is $\mathcal{O}(N^3)$, and the upper bound for space complexity is $\mathcal{O}(N^2)$.

Once we solve for α^t, we see that though there are N of them, most vanish with $\alpha^t = 0$ and only a small percentage have $\alpha^t > 0$. The set of $\mathbf{x}^t$ whose $\alpha^t > 0$ are the *support vectors*, and as we see in equation 10.50, $\mathbf{w}$ is written as the weighted sum of these training instances that are selected as the support vectors. These are the $\mathbf{x}^t$, which satisfy

$$r^t(\mathbf{w}^T\mathbf{x}^t + w_0) = 1$$

and lie on the margin. We can use this fact to calculate w_0 from any support vector as

$$w_0 = r^t - \mathbf{w}^T\mathbf{x}^t \tag{10.53}$$

For numerical stability, it is advised that this is done for all support vectors and an average is taken. The discriminant thus found is called the *support vector machine* (SVM).

SUPPORT VECTOR MACHINE

The majority of the α^t are 0, for which $r^t(\mathbf{w}^T\mathbf{x}^t + w_0) > 1$. These are the $\mathbf{x}^t$ that lie further inside of the margin and have no effect on the hyperplane. From this perspective, this algorithm can be likened to the condensed nearest neighbor algorithm (section 8.5), which stores only the instances defining the class discriminant. Being a discriminant-based method, the SVM cares only about the instances close to the boundary and discards those that lie in the interior. Using this idea, it is possible to use a simpler classifier before the SVM to filter out a large portion of such instances thereby decreasing the complexity of the optimization step of the SVM.

During testing, we do not enforce a margin. We calculate $g(\mathbf{x}) = \mathbf{w}^T\mathbf{x} + w_0$, and choose according to the sign of $g(\mathbf{x})$:

Choose C_1 if $g(\mathbf{x}) > 0$ and C_2 otherwise

When there are $K > 2$ classes, the straightforward way is to define K two-class problems, each one separating one class from all other classes combined and learn K support vector machines $g_i(\mathbf{x}), i = 1, \ldots, K$. During testing, we calculate all $g_i(\mathbf{x})$ and choose the maximum.

10.9.2 The Nonseparable Case: Soft Margin Hyperplane

If the data is not linearly separable, the algorithm we discussed earlier will not work. In such a case, if the two classes are not linearly separable such that there is no hyperplane to separate them, we look for the

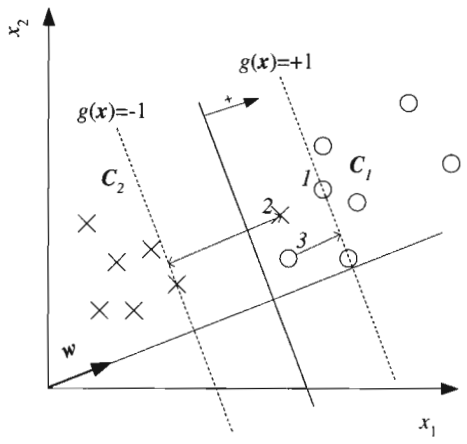

Figure 10.12 In classifying an instance, there are three possible cases: In (1), $\xi = 0$; it is on the right side and sufficiently away. In (2), $\xi = 1 + g(\mathbf{x}) > 1$; it is on the wrong side. In (3), $\xi = 1 - g(\mathbf{x}), 0 < \xi < 1$; it is on the right side but is in the margin and not sufficiently away.

SLACK VARIABLES

one that incurs the least error. We define *slack variables*, $\xi^t \geq 0$, which store the deviation from the margin. There are two types of deviation: An instance may lie on the wrong side of the hyperplane and be misclassified. Or, it may be on the right side but may lie in the margin, namely, not sufficiently away from the hyperplane. Relaxing equation 10.46, we require

$$r^t(\mathbf{w}^T\mathbf{x}^t + w_0) \geq 1 - \xi^t \tag{10.54}$$

If $\xi^t = 0$, there is no problem with $\mathbf{x}^t$. If $0 < \xi^t < 1$, $\mathbf{x}^t$ is correctly classified but it is in the margin. If $\xi^t \geq 1$, $\mathbf{x}^t$ is misclassified (see figure 10.12). The number of misclassifications is $\#\{\xi^t > 1\}$, and the number of non-

SOFT ERROR

separable points is $\#\{\xi_t > 0\}$. We define *soft error* as

$$\sum_t \xi^t$$

and add this as a penalty term to the primal of equation 10.49:

$$L_p = \frac{1}{2}\|\mathbf{w}\|^2 + C\sum_t \xi^t - \sum_t \alpha^t[r^t(\mathbf{w}^T\mathbf{x}^t + w_0) - 1 + \xi^t] - \sum_t \mu^t\xi^t \tag{10.55}$$

where μ_t are the new Lagrange parameters to guarantee the positivity of ξ^t. C is the penalty factor as in any regularization scheme trading off

complexity (number of support vectors) and data misfit (number of nonseparable points). Note that we are penalizing not only the misclassified points but also the ones in the margin for better generalization, though these latter would be correctly classified during testing.

The dual problem is

$$L_d = \sum_t \alpha^t - \frac{1}{2}\sum_t \sum_s \alpha^t \alpha^s r^t r^s (\mathbf{x}^t)^T \mathbf{x}^s \tag{10.56}$$

subject to

$$\sum_t \alpha^t r^t = 0 \text{ and } 0 \le \alpha^t \le C, \forall t$$

As in the separable case, instances that are not support vectors vanish with their $\alpha^t = 0$ and the remaining define $\mathbf{w}$. w_0 is then solved for similarly.

10.9.3 Kernel Functions

Section 10.2 demonstrated that if the problem is nonlinear, instead of trying to fit a nonlinear model, we can map the problem to a new space by doing a nonlinear transformation using suitably chosen basis functions and then use a linear model in this new space. The linear model in the new space corresponds to a nonlinear model in the original space. This approach can be used in both classification and regression problems, and in the special case of classification, it can be used with any scheme. In the particular case of support vector machines, it leads to certain simplifications as we see here.

Let us say we have the new dimensions calculated through the basis functions

$$\mathbf{z} = \boldsymbol{\phi}(\mathbf{x}) \text{ where } z_j = \phi_j(\mathbf{x}), j = 1, \ldots, k$$

mapping from the d-dimensional $\mathbf{x}$ space to the k-dimensional $\mathbf{z}$ space where we write the discriminant as

$$\begin{aligned} g(\mathbf{z}) &= \mathbf{w}^T \mathbf{z} \\ g(\mathbf{x}) &= \mathbf{w}^T \boldsymbol{\phi}(\mathbf{x}) \\ &= \sum_{j=1}^{k} w_j \phi_j(\mathbf{x}) \end{aligned} \tag{10.57}$$

where we do not use a separate w_0; we assume that $z_1 = \phi_1(\boldsymbol{x}) \equiv 1$. Generally, k is much larger than d and k is also larger than N, and there is the advantage of using the dual form whose complexity depends on N, whereas if we used the primal it would depend on k. We also use the more general case of the soft margin hyperplane here because we have no guarantee that the problem is linearly separable in this new space. However, it is critical here, as in any regularization scheme, that a proper value is chosen for C, the penalty factor. If it is too large, we have a high penalty for nonseparable points and we may store many support vectors and overfit. If it is too small, we may have underfitting.

The solution is

$$\boldsymbol{w} = \sum_t \alpha^t r^t \boldsymbol{z}^t = \sum_t \alpha^t r^t \boldsymbol{\phi}(\boldsymbol{x}^t) \tag{10.58}$$

and the discriminant is

$$g(\boldsymbol{x}) = \boldsymbol{w}^T \boldsymbol{\phi}(\boldsymbol{x}) = \sum_t \alpha^t r^t \boldsymbol{\phi}(\boldsymbol{x}^t)^T \boldsymbol{\phi}(\boldsymbol{x}) \tag{10.59}$$

KERNEL MACHINE
KERNEL FUNCTION

The idea in *kernel machines* is to replace the inner product of basis functions, $\boldsymbol{\phi}(\boldsymbol{x}^t)^T \boldsymbol{\phi}(\boldsymbol{x})$, by a *kernel function*, $K(\boldsymbol{x}^t, \boldsymbol{x})$, between the support vectors and the input in the original input space:

$$g(\boldsymbol{x}) = \sum_t \alpha^t r^t K(\boldsymbol{x}^t, \boldsymbol{x}) \tag{10.60}$$

The most popular kernel functions are

- *polynomials* of degree q:

$$K(\boldsymbol{x}^t, \boldsymbol{x}) = (\boldsymbol{x}^T \boldsymbol{x}^t + 1)^q$$

where q is selected by the user. For example, when $q = 2$ and $d = 2$,

$$\begin{aligned} K(\boldsymbol{x}, \boldsymbol{y}) &= (\boldsymbol{x}^T \boldsymbol{y} + 1)^2 \\ &= (x_1 y_1 + x_2 y_2 + 1)^2 \\ &= 1 + 2x_1 y_1 + 2x_2 y_2 + 2x_1 x_2 y_1 y_2 + x_1^2 y_1^2 + x_2^2 y_2^2 \end{aligned}$$

which corresponds to the inner product of the basis function (Cherkassky and Mulier 1998):

$$\boldsymbol{\phi}(\boldsymbol{x}) = [1, \sqrt{2}x_1, \sqrt{2}x_2, \sqrt{2}x_1 x_2, x_1^2, x_2^2]^T$$

- *radial-basis functions:*

$$K(\boldsymbol{x}^t, \boldsymbol{x}) = \exp\left[-\frac{\|\boldsymbol{x}^t - \boldsymbol{x}\|^2}{\sigma^2}\right]$$

  which defines a spherical kernel as in Parzen windows (chapter 8) where $\boldsymbol{x}^t$ is the center and σ, supplied by the user, defines the radius. This is similar to radial basis functions that we discuss in chapter 12.

- *sigmoidal functions:*

$$K(\boldsymbol{x}^t, \boldsymbol{x}) = \tanh(2\boldsymbol{x}^T\boldsymbol{x}^t + 1)$$

  where $\tanh(\cdot)$ has the same shape with sigmoid, except that it ranges between -1 and $+1$. This is similar to multilayer perceptrons that we discuss in chapter 11.

Other kernel functions are also possible, subject to certain conditions (Vapnik 1995; Cherkassky and Mulier 1998).

Cortes and Vapnik (1995) report excellent results with the SVM on a handwritten digit recognition application. Inputs are 16×16 bitmaps and thus are 256-dimensional. In this case, using a polynomial kernel with $q = 3$ implies a feature space of 10^6 dimensions. The results indicate no overfitting on a training set of 7,300 instances, with on the average 148 instances chosen as support vectors.

Vapnik (1995) has shown that the expected test error rate is

$$E_N[P(error)] \leq \frac{E_N[\#\text{ of support vectors}]}{N}$$

where $E_N[\cdot]$ denotes expectation over training sets of size N. Therefore, the error rate depends on the number of support vectors and not on the input dimensionality.

10.9.4 Support Vector Machines for Regression

Although this chapter is on classification, it is instructive to briefly discuss how support vector machines can be generalized to regression. We use a linear model:

$$f(\boldsymbol{x}) = \boldsymbol{w}^T\boldsymbol{x} + w_0$$

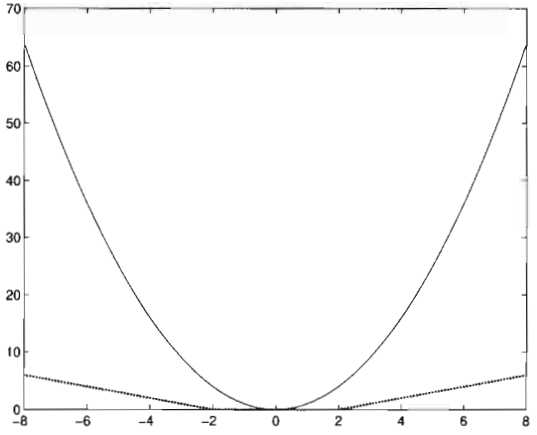

Figure 10.13 Quadratic and ϵ-sensitive error functions. We see that ϵ-sensitive error function is not affected by small errors and also is affected less by large errors and thus is more robust to outliers.

In regression, we use the square of the difference as error:

$$e_2(r^t, f(\boldsymbol{x}^t)) = [r^t - f(\boldsymbol{x}^t)]^2$$

whereas in support vector regression, we use the ϵ-sensitive loss function:

$$e_\epsilon(r^t, f(\boldsymbol{x}^t)) = \begin{cases} 0 & \text{if } |r^t - f(\boldsymbol{x}^t)| < \epsilon \\ |r^t - f(\boldsymbol{x}^t)| - \epsilon & \text{otherwise} \end{cases} \tag{10.61}$$

which means that we tolerate errors up to ϵ and also that errors beyond have a linear effect and not quadratic. This error function is therefore more tolerant to noise and is thus more *robust* (see figure 10.13).

ROBUST REGRESSION

Analogous to the soft margin hyperplane, we introduce slack variables to account for deviations out of the ϵ-zone and we get (Vapnik 1995)

$$\min \frac{1}{2}\|\boldsymbol{w}\|^2 + C\sum_t (\xi_+^t + \xi_-^t) \tag{10.62}$$

subject to

$$\begin{aligned} r^t - (\boldsymbol{w}^T\boldsymbol{x} + w_0) &\leq \epsilon + \xi_+^t \\ (\boldsymbol{w}^T\boldsymbol{x} + w_0) - r^t &\leq \epsilon + \xi_-^t \\ \xi_+^t, \xi_-^t &\geq 0 \end{aligned}$$

where we used two types of slack variables, for positive and negative deviations, to keep them positive. This formulation corresponds to the ϵ-sensitive loss function given in equation 10.61.

As given in Vapnik (1995), one can write this as a Lagrange function and then take its dual. Kernel functions can also be used here. As in classification, the result will choose certain training instances as support vectors, and the regression line is written as a weighted sum of them.

10.10 Notes

Linear discriminant due to its simplicity, is the topic most worked on in pattern recognition (Duda, Hart, and Stork 2001; McLachlan 1992). We discussed the case of Gaussian distributions with a common covariance matrix in chapter 4 and Fisher's linear discriminant in chapter 6, and in this chapter, we surveyed other approaches up to the most recent approach of support vector machines. In chapter 11, we discuss the perceptron that is the neural network implementation of the linear discriminant.

Logistic discrimination is discussed in more detail in Anderson 1982 and in McLachlan 1992. Logistic (sigmoid) is the inverse of logit, which is the *canonical link* in case of Bernoulli samples. Softmax is its generalization to multinomial samples. More information on such *generalized linear models* is given in McCullogh and Nelder 1989.

GENERALIZED LINEAR MODELS

More information on support vector machines can be found in books by Vapnik (1995; 1998). The chapter on SVM in Cherkassky and Mulier 1998 is very readable. Burges 1998 and Smola and Schölkopf 1998 are good tutorials on SVM classification and regression, respectively. There are also two dedicated Web sites that contain example applets and links to tutorials and papers on SVM, at http://svm.research.bell-labs.com and http://www.kernel-machines.org

10.11 Exercises

1. For each of the following basis function, describe where it is nonzero:
   a. $\sin(x_1)$
   b. $\exp(-(x_1 - a)^2/c)$
   c. $\exp(-\|\boldsymbol{x} - \boldsymbol{a}\|^2/c)$

d. $\log(x_2)$

e. $1(x_1 > c)$

f. $1(ax_1 + bx_2 > c)$

2. For the two-dimensional case of figure 10.2, show equations 10.4 and 10.5.
3. Show that the derivative of the softmax, $y_i = \exp(a_i) / \sum_j \exp(a_j)$, is $\partial y_i / \partial a_j = y_i(\delta_{ij} - y_j)$, where δ_{ij} is 1 if $i = j$ and 0 otherwise.
4. With $K = 2$, show that using two softmax outputs is equal to using one sigmoid output.
5. How can we learn $\mathbf{W}_i$ in equation 10.34?

11 *Multilayer Perceptrons*

The multilayer perceptron is an artificial neural network structure and is a nonparametric estimator that can be used for classification and regression. We discuss the backpropagation algorithm to train a multilayer perceptron for a variety of applications.

11.1 Introduction

ARTIFICIAL NEURAL network models, one of which is the *perceptron* we discuss in this chapter, take their inspiration from the brain. There are cognitive scientists and neuroscientists whose aim is to understand the functioning of the brain (Posner 1989), and toward this aim, build models of the natural neural networks in the brain and make simulation studies.

ARTIFICIAL NEURAL NETWORKS

However, in engineering, our aim is not to understand the brain per se, but to build useful machines. We are interested in *artificial neural networks* because we believe that they may help us build better computer systems. The brain is an information processing device that has some incredible abilities and surpasses current engineering products in many domains, for example; vision, speech recognition, and learning, to name three. These applications have evident economic utility if implemented on machines. If we can understand how the brain performs these functions, we can define solutions to these tasks as formal algorithms and implement them on computers.

NEURONS

The human brain is quite different from a computer. Whereas a computer generally has one processor, the brain is composed of a very large (10^{11}) number of processing units, namely, *neurons,* operating in parallel. Though the details are not known, the processing units are believed to be

much simpler and slower than a processor in a computer. What also makes the brain different, and is believed to provide its computational power, is the large connectivity: Neurons in the brain have connections, called *synapses,* to around 10^4 other neurons, all operating in parallel. In a computer, the processor is active and the memory is separate and passive, but it is believed that in the brain, both the processing and memory are distributed together over the network; processing is done by the neurons, and the memory is in the synapses between the neurons.

SYNAPSES

11.1.1 Understanding the Brain

According to Marr (1982), understanding an information processing system has three levels, called the *levels of analysis:*

LEVELS OF ANALYSIS

1. *Computational theory* corresponds to the goal of computation and an abstract definition of the task.

2. *Representation and algorithm* is about how the input and the output are represented and about the specification of the algorithm for the transformation from the input to the output.

3. *Hardware implementation* is the actual physical realization of the system.

One example is sorting: The computational theory is to order a given set of elements. The representation may use integers, and the algorithm may be Quicksort. After compilation, the executable code for a particular processor sorting integers represented in binary is one hardware implementation.

The idea is that for the same computational theory, there may be multiple representations and algorithms manipulating symbols in that representation. Similarly, for any given representation and algorithm, there may be multiple hardware implementations. We can use one of various sorting algorithms, and even the same algorithm can be compiled on computers with different processors and lead to different hardware implementations.

To take another example, '6', 'VI', and '110' are three different representations of the number six. There is a different algorithm for addition depending on the representation used. Digital computers use binary representation and have circuitry to add in this representation, which is one

particular hardware implementation. Numbers are represented differently, and addition corresponds to a different set of instructions on an abacus, which is another hardware implementation. When we add two numbers in our head, we use another representation and an algorithm suitable to that representation, which is implemented by the neurons. But all these different hardware implementations—for example, we, abacus, digital computer—implement the same computational theory which is addition.

The classic example is the difference between natural and artificial flying machines: A sparrow flaps its wings; a commercial airplane does not flap its wings but uses jet engines. The sparrow and the airplane are two hardware implementations built for different purposes, satisfying different constraints. But they both implement the same theory, which is aerodynamics.

The brain is one hardware implementation for learning or pattern recognition. If from this particular implementation, we can do reverse engineering and extract the representation and the algorithm used, and if from that in turn, we can get the computational theory, we can then use another representation and algorithm, and in turn a hardware implementation more suited to the means and constraints we have. One hopes our implementation will be cheaper, faster, and more accurate.

Just as the initial attempts to build flying machines looked very much like birds until we discovered aerodynamics, it is also expected that the first attempts to build structures possessing brain's abilities will look like the brain with networks of large numbers of processing units, until we discover the computational theory of intelligence. So it can be said that in understanding the brain, when we are working on artificial neural networks, we are at the representation and algorithm level.

Just as the feathers are irrelevant to flying, in time we may discover that neurons and synapses are irrelevant to intelligence. But until that time there is one other reason why we are interested in understanding the functioning of the brain, and that is related to parallel processing.

11.1.2 Neural Networks as a Paradigm for Parallel Processing

Since the 1980s, computer systems with thousands of processors have been commercially available. The software for such parallel architectures, however, has not advanced as quickly as hardware. The reason for this is that almost all our theory of computation up to that point was based

on serial, one processor machines. We are not able to use the parallel machines we have efficiently because we cannot program them efficiently.

PARALLEL PROCESSING

There are mainly two paradigms for *parallel processing:* In Single Instruction Multiple Data (SIMD) machines, all processors execute the same instruction but on different pieces of data. In Multiple Instruction Multiple Data (MIMD) machines, different processors may execute different instructions on different data. SIMD machines are easier to program because there is only one program to write. However, problems rarely have such a regular structure that they can be parallelized over a SIMD machine. MIMD machines are more general, but it is not an easy task to write separate programs for all the individual processors; additional problems are related to synchronization, data transfer between processors, and so forth. SIMD machines are also easier to build, and machines with more processors can be constructed if they are SIMD. In MIMD machines, processors are more complex, and a more complex communication network should be constructed for the processors to exchange data arbitrarily.

Assume now that we can have machines where processors are a little bit more complex than SIMD processors but not as complex as MIMD processors. Assume we have simple processors with a small amount of local memory where some parameters can be stored. Each processor implements a fixed function and executes the same instructions as SIMD processors; but by loading different values into the local memory, they can be doing different things and the whole operation can be distributed over such processors. We will then have what we can call Neural Instruction Multiple Data (NIMD) machines, where each processor corresponds to a neuron, local parameters correspond to its synaptic weights, and the whole structure is a neural network. If the function implemented in each processor is simple and if the local memory is small, then many such processors can be fitted on a single chip.

The problem now is to distribute a task over a network of such processors and to determine the local parameter values. This is where learning comes into play: We do not need to program such machines and determine the parameter values ourselves if such machines can learn from examples.

Thus, artificial neural networks are a way to make use of the parallel hardware we can build with current technology and—thanks to learning—they need not be programmed. Therefore, we also save ourselves the effort of programming them.

In this chapter, we discuss such structures and how they are trained.

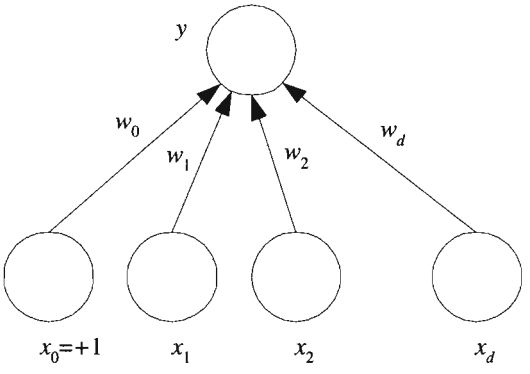

Figure 11.1 Simple perceptron. $x_j, j = 1, \ldots, d$ are the input units. x_0 is the bias unit that always has the value 1. y is the output unit. w_j is the weight of the directed connection from input x_j to the output.

Keep in mind that the operation of an artificial neural network is a mathematical function that can be implemented on a serial computer—as it generally is—and training the network is not much different from statistical techniques that we have discussed in the previous chapters. Thinking of this operation as being carried out on a network of simple processing units is meaningful only if we have the parallel hardware, and only if the network is so large that it cannot be simulated fast enough on a serial computer.

11.2 The Perceptron

PERCEPTRON

The *perceptron* is the basic processing element. It has inputs that may come from the environment or may be the outputs of other perceptrons.

CONNECTION WEIGHT
SYNAPTIC WEIGHT

Associated with each input, $x_j \in \Re, j = 1, \ldots, d$, is a *connection weight*, or *synaptic weight* $w_j \in \Re$, and the output, y, in the simplest case is a weighted sum of the inputs (see figure 11.1):

$$y = \sum_{j=1}^{d} w_j x_j + w_0 \tag{11.1}$$

BIAS UNIT

w_0 is the intercept value to make the model more general; it is generally modeled as the weight coming from an extra *bias unit*, x_0, which is always

+1. We can write the output of the perceptron as a dot product

$$y = \mathbf{w}^T\mathbf{x} \tag{11.2}$$

where $\mathbf{w} = [w_0, w_1, \ldots, w_d]^T$ and $\mathbf{x} = [1, x_1, \ldots, x_d]^T$ are *augmented* vectors to include also the bias weight and input.

During testing, with given weights, $\mathbf{w}$, for input $\mathbf{x}$, we compute the output y. To implement a given task, we need to *learn* the weights $\mathbf{w}$, the parameters of the system, such that correct outputs are generated given the inputs.

When $d = 1$ and x is fed from the environment through an input unit, we have

$$y = wx + w_0$$

which is the equation of a line with w as the slope and w_0 as the intercept. Thus this perceptron with one input and one output can be used to implement a linear fit. With more than one input, the line becomes a (hyper)plane, and the perceptron with more than one input can be used to implement multivariate linear fit. Given a sample, the parameters w_j can be found by regression (see section 5.8).

The perceptron as defined in equation 11.1 defines a hyperplane and as such can be used to divide the input space into two: the half-space where it is positive and the half-space where it is negative (see chapter 10). By using it to implement a linear discriminant function, the perceptron can separate two classes by checking the sign of the output. If we define $s(\cdot)$ as the *threshold function*

THRESHOLD FUNCTION

$$s(a) = \begin{cases} 1 & \text{if } a > 0 \\ 0 & \text{otherwise} \end{cases} \tag{11.3}$$

then we can

$$\text{choose} \begin{cases} C_1 & \text{if } s(\mathbf{w}^T\mathbf{x}) > 0 \\ C_2 & \text{otherwise} \end{cases}$$

Remember that using a linear discriminant assumes that classes are linearly separable. That is to say, it is assumed that a hyperplane $\mathbf{w}^T\mathbf{x} = 0$ can be found that separates $\mathbf{x}^t \in C_1$ and $\mathbf{x}^t \in C_2$. If at a later stage we need the posterior probability—for example, to calculate risk—we need to use the sigmoid function at the output as

$$\begin{aligned} o &= \mathbf{w}^T\mathbf{x} \\ y &= \text{sigmoid}(o) = \frac{1}{1 + \exp[-\mathbf{w}^T\mathbf{x}]} \end{aligned} \tag{11.4}$$

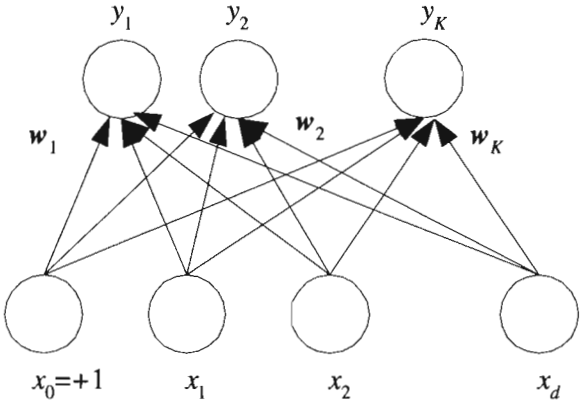

Figure 11.2 K parallel perceptrons. $x_j, j = 0, \ldots, d$ are the inputs and $y_i, i = 1, \ldots, K$ are the outputs. w_{ij} is the weight of the connection from input x_j to output y_i. Each output is a weighted sum of the inputs. When used for K-class classification problem, there is a postprocessing to choose the maximum, or softmax if we need the posterior probabilities.

When there are $K > 2$ outputs, there are K perceptrons, each of which has a weight vector $\mathbf{w}_i$ (see figure 11.2)

$$y_i = \sum_{j=1}^{d} w_{ij} x_j + w_{i0} = \mathbf{w}_i^T \mathbf{x}$$

$$\mathbf{y} = \mathbf{W}\mathbf{x} \tag{11.5}$$

where w_{ij} is the weight from input x_j to output y_i. $\mathbf{W}$ is the $K \times (d + 1)$ weight matrix of w_{ij} whose rows are the weight vectors of the K perceptrons. When used for classification, during testing, we

$$\text{choose } C_i \text{ if } y_i = \max_k y_k$$

In the case of a neural network, the value of each perceptron is a *local* function of its inputs and its synaptic weights. However in classification, if we need the posterior probabilities (instead of just the code of the winner class) and use the softmax, we also need the values of the other outputs. So, to implement this as a neural network, we can see this as a two-stage process, where the first stage calculates the weighted sums, and the second stage calculates the softmax values; but we still denote

this as a single layer of output units:

$$o_i = \mathbf{w}_i^T \mathbf{x}$$
$$y_i = \frac{\exp o_i}{\sum_k \exp o_k} \tag{11.6}$$

Remember that by defining auxiliary inputs, the linear perceptron can also be used for polynomial approximation, for example, define $x_3 = x_1^2, x_4 = x_2^2, x_5 = x_1 x_2$ (section 10.2). The same can also be used with perceptrons (Durbin and Rumelhart 1989). In section 11.5, we see multilayer perceptrons where such nonlinear functions are learned from data instead of being assumed a priori.

Any of the methods discussed in chapter 10 on linear discrimination can be used to calculate $\mathbf{w}_i, i = 1, \ldots, K$ offline and then plugged into the network. These include parametric approach with a common covariance matrix, logistic discrimination, discrimination by regression, and support vector machines. In some cases, we do not have the whole sample at hand when training starts, and we need to iteratively update parameters as new examples arrive; we discuss this case of *online* learning in section 11.3.

Equation 11.5 defines a linear transformation from a d-dimensional space to a K-dimensional space and can also be used for dimensionality reduction if $K < d$. One can use any of the methods of chapter 6 to calculate $\mathbf{W}$ offline and then use the perceptrons to implement the transformation, for example, PCA. In such a case, we have a two-layer network where the first layer of perceptrons implements the linear transformation and the second layer implements the linear regression or classification in the new space. We note that because both are linear transformations, they can be combined and written down as a single layer. We will see the more interesting case where the first layer implements *nonlinear* dimensionality reduction in section 11.5.

11.3 Training a Perceptron

The perceptron defines a hyperplane, and the neural network perceptron is just a way of *implementing* the hyperplane. Given a data sample, the weight values can be calculated *offline* and then when they are plugged in, the perceptron can be used to calculate the output values.

In training neural networks, we generally use online learning where we are not given the whole sample, but we are given instances one by one and would like the network to update its parameters after each instance,

adapting itself slowly in time. Such an approach is interesting for a number of reasons:

1. It saves us from storing the training sample in an external memory and storing the intermediate results during optimization. An approach like support vector machines (section 10.9) may be quite costly with large samples, and in some applications, we may prefer a simpler approach where we do not need to store the whole sample and solve a complex optimization problem on it.

2. The problem may be changing in time, which means that the sample distribution is not fixed, and a training set cannot be chosen a priori. For example, we may be implementing a speech recognition system that adapts itself to its user.

3. There may be physical changes in the system. For example, in a robotic system, the components of the system may wear out, or sensors may degrade.

ONLINE LEARNING

In *online learning,* we do not write the error function over the whole sample but on individual instances. Starting from random initial weights, at each iteration we adjust the parameters a little bit to minimize the error, without forgetting what we have previously learned. If this error function is differentiable, we can use gradient descent.

For example, in regression the error on the single instance pair with index t, (x^t, r^t), is

$$E^t(\mathbf{w}|\mathbf{x}^t, r^t) = \frac{1}{2}(r^t - y^t)^2 = \frac{1}{2}[r^t - (\mathbf{w}^T\mathbf{x}^t)]^2$$

and for $j = 0, \ldots, d$, the online update is

$$\Delta w_j^t = \eta(r^t - y^t)x_j^t \tag{11.7}$$

where η is the learning factor, which is gradually decreased in time for convergence. This is known as *stochastic gradient descent.*

STOCHASTIC GRADIENT DESCENT

Similarly, update rules can be derived for classification problems using logistic discrimination where updates are done after each pattern, instead of summing them and doing the update after a complete pass over the training set. With two classes, for the single instance $(\mathbf{x}^t, r^t)$ where $r_i^t = 1$ if $\mathbf{x}^t \in C_1$ and $r_i^t = 0$ if $\mathbf{x}^t \in C_2$, the single output is

$$y^t = \text{sigmoid}(\mathbf{w}^T\mathbf{x}^t)$$

and the cross-entropy is

$$E^t(\{\mathbf{w}_i\}_i|\mathbf{x}^t,\mathbf{r}^t) = -\sum_i r_i^t \log y_i^t + (1-r_i^t)\log(1-y_i^t)$$

Using gradient descent, we get the following online update rule $j = 0,\ldots,d$:

$$\Delta w_j^t = \eta(r^t - y^t)x_j^t \tag{11.8}$$

When there are $K > 2$ classes, for the single instance $(\mathbf{x}^t,\mathbf{r}^t)$ where $r_i^t = 1$ if $\mathbf{x}^t \in C_i$ and 0 otherwise, the outputs are

$$y_i^t = \frac{\exp \mathbf{w}_i^T\mathbf{x}^t}{\sum_k \exp \mathbf{w}_k^T\mathbf{x}^t}$$

and the cross-entropy is

$$E^t(\{\mathbf{w}_i\}_i|\mathbf{x}^t,\mathbf{r}^t) = -\sum_i r_i^t \log y_i^t$$

Using gradient descent, we get the following online update rule, for $i = 1,\ldots,K,\ j = 0,\ldots,d$:

$$\Delta w_{ij}^t = \eta(r_i^t - y_i^t)x_j^t \tag{11.9}$$

which is the same as the equations we saw in section 10.7 except that we do not sum over all of the instances but update after a single instance. The pseudocode of the algorithm is given in figure 11.3, which is the online version of figure 10.8.

Both equations 11.7 and 11.9 have the form

$$\text{Update} = \text{LearningFactor} \cdot (\text{DesiredOutput} - \text{ActualOutput}) \cdot \text{Input} \tag{11.10}$$

Let us try to get some insight into what this does: First, if the actual output is equal to the desired output, no update is done. When it is done, the magnitude of the update increases as the difference between the desired output and the actual output increases. We also see that if the actual output is less than the desired output, update is positive if the input is positive and negative if the input is negative. This has the effect of increasing the actual output and decreasing the difference. If the actual output is greater than the desired output, update is negative if the input is positive and positive if the input is negative; this decreases the actual output and makes it closer to the desired output.

```
For i = 1,...,K
    For j = 0,...,d

Until convergence
```

Figure 11.3 Percepton training algorithm implementing stochastic online gradient-descent for the case with $K > 2$ classes. This is the online version of the algorithm given in figure 10.8.

When an update is done, its magnitude depends also on the input. If the input is close to 0, its effect on the actual output is small and therefore its weight is also updated by a small amount. The greater an input, the greater the update of its weight.

Finally, the magnitude of the update depends on the learning factor, η. If it is too large, updates depend too much on recent instances; it is as if the system has a very short memory. If this factor is small, many updates may be needed for convergence. In section 11.8.1, we discuss methods to speed up convergence.

11.4 Learning Boolean Functions

In a Boolean function, the inputs are binary and the output is 1 if the corresponding function value is true and 0 otherwise. Therefore, it can be seen as a two-class classification problem. As an example, for learning to AND two inputs, the table of inputs and required outputs is given in table 11.1. An example of a perceptron that implements AND and its

Table 11.1 Input and output for the AND function.

x_1	x_2	r
0	0	0
0	1	0
1	0	0
1	1	1

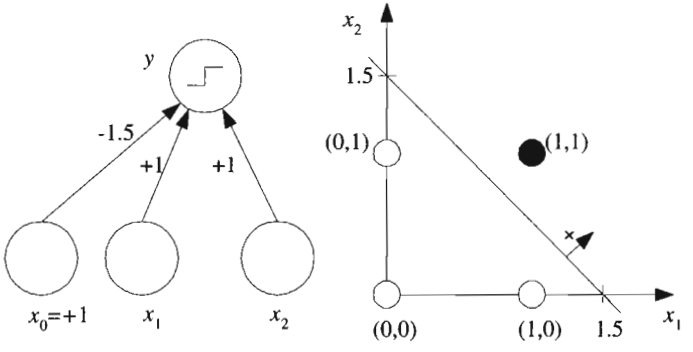

Figure 11.4 The perceptron that implements AND and its geometric interpretation.

geometric interpretation in two dimensions is given in figure 11.4. The discriminant is

$$y = s(x_1 + x_2 - 1.5)$$

that is, $\boldsymbol{x} = [1, x_1, x_2]^T$ and $\boldsymbol{w} = [-1.5, 1, 1]^T$. Note that $y = x_1 + x_2 - 1.5$ satisfies the four constraints given by the definition of AND function in table 11.1, for example, for $x_1 = 1, x_2 = 0$, $y = s(-0.5) = 0$. Similarly it can be shown that $y = s(x_1 + x_2 - 0.5)$ implements OR.

Though Boolean functions like AND and OR are linearly separable and are solvable using the perceptron, certain functions like XOR are not. The table of inputs and required outputs for XOR is given in table 11.2. As can be seen in figure 11.5, the problem is not linearly separable. This can also be proved by noting that there are no w_0, w_1, and w_2 values that

Table 11.2 Input and output for the XOR function.

x_1	x_2	r
0	0	0
0	1	1
1	0	1
1	1	0

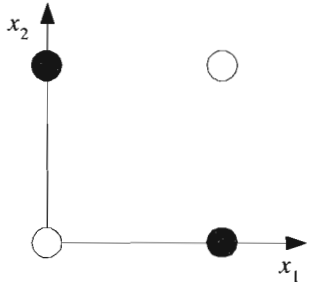

Figure 11.5 XOR problem is not linearly separable. We cannot draw a line where the empty circles are on one side and the filled circles on the other side.

satisfy the following set of inequalities:

$$\begin{aligned} & & w_0 & \leq 0 \\ & w_2+ & w_0 & > 0 \\ w_1+ & & w_0 & > 0 \\ w_1+ & w_2+ & w_0 & \leq 0 \end{aligned}$$

This result should not be very surprising to us since the VC dimension of a line (in two dimensions) is three. With two binary inputs there are four cases and thus we know that there exist problems with two inputs that are not solvable using a line; XOR is one of them.

11.5 Multilayer Perceptrons

A perceptron that has a single layer of weights can only approximate linear functions of the input and cannot solve problems like the XOR, where the discrimininant to be estimated is nonlinear. Similarly a perceptron

HIDDEN LAYERS
MULTILAYER PERCEPTRONS

cannot be used for nonlinear regression. This limitation does not apply to feedforward networks with intermediate or *hidden layers* between the input and the output layers. If used for classification, such *multilayer perceptrons* (MLP) can implement nonlinear discriminants and, if used for regression, can approximate nonlinear functions of the input.

Input $\boldsymbol{x}$ is fed to the input layer (including the bias), the "activation" propagates in the forward direction, and the values of the hidden units z_h are calculated (see figure 11.6). Each hidden unit is a perceptron by itself and applies the nonlinear sigmoid function to its weighted sum:

$$z_h = \text{sigmoid}(\boldsymbol{w}_h^T \boldsymbol{x}) = \frac{1}{1 + \exp\left[-\left(\sum_{j=1}^{d} w_{hj} x_j + w_{h0}\right)\right]}, \quad h = 1, \ldots, H \tag{11.11}$$

The output y_i are perceptrons in the second layer taking the hidden units as their inputs

$$y_i = \boldsymbol{v}_i^T \boldsymbol{z} = \sum_{h=1}^{H} v_{ih} z_h + v_{i0} \tag{11.12}$$

where there is also a bias unit in the hidden layer, which we denote by z_0, and v_{i0} are the bias weights. The input layer of x_j is not counted since no computation is done there and when there is a hidden layer, this is a two-layer network.

As usual, in a regression problem, there is no nonlinearity in the output layer in calculating y. In a two-class discrimination task, there is one sigmoid output unit and when there are $K > 2$ classes, there are K outputs with softmax as the output nonlinearity.

If the hidden units' outputs were linear, the hidden layer would be of no use: Linear combination of linear combinations is another linear combination. Sigmoid is the continuous, differentiable version of thresholding. We need differentiability because the learning equations we will see are gradient-based. Another sigmoid (S-shaped) nonlinear basis function that can be used is the hyperbolic tangent function, tanh, which ranges from -1 to $+1$, instead of 0 to $+1$. In practice, there is no difference between using the sigmoid and the tanh. Still another possibility is the Gaussian, which uses Euclidean distance instead of the dot product for similarity; we discuss such radial basis function networks in chapter 12.

The output is a linear combination of the nonlinear basis function values computed by the hidden units. It can be said that the hidden units make a nonlinear transformation from the d-dimensional input space to

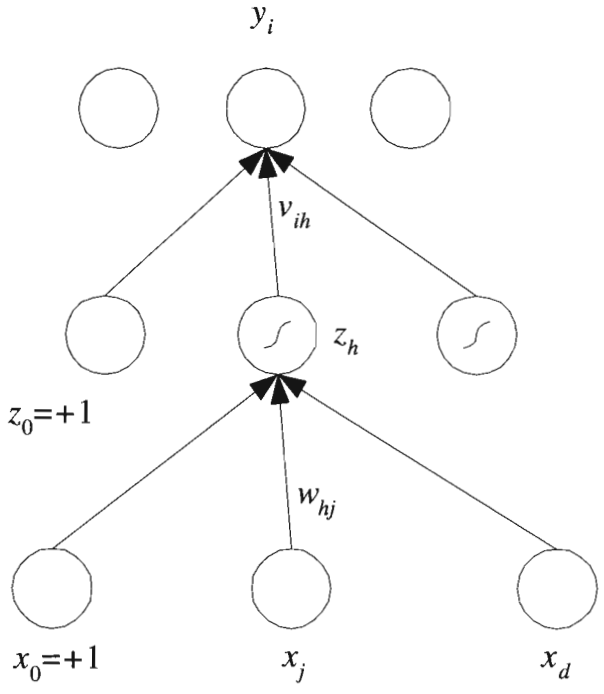

Figure 11.6 The structure of a multilayer perceptron. $x_j, j = 0, \ldots, d$ are the inputs, $z_h, h = 1, \ldots, H$ are the hidden units where H is the dimensionality of this hidden space. z_0 is the bias of the hidden layer. $y_i, i = 1, \ldots, K$ are the output units. w_{hj} are weights in the first layer, and v_{ih} are the weights in the second layer.

the H-dimensional space spanned by the hidden units, and in this space, the second output layer implements a linear function.

One is not limited to having one hidden layer, and more hidden layers with their own incoming weights can be placed after the first hidden layer with sigmoid hidden units, thus calculating nonlinear functions of the first layer of hidden units and implementing more complex functions of the inputs. In practice, people rarely go beyond one hidden layer since analyzing a network with many hidden layers is quite complicated; but sometimes when the hidden layer contains too many hidden units, it may be sensible to go to multiple hidden layers, preferring "long and narrow" networks to "short and fat" networks.

11.6 MLP as a Universal Approximator

We can represent any Boolean function as a disjunction of conjunctions, and such a Boolean expression can be implemented by a multilayer perceptron with one hidden layer. Each conjunction is implemented by one hidden unit and the disjunction by the output unit. For example,

$$x_1 \text{ XOR } x_2 = (x_1 \text{ AND } \sim x_2) \text{ OR } (\sim x_1 \text{ AND } x_2)$$

We have seen previously how to implement AND and OR using perceptrons. So two perceptrons can in parallel implement the two AND, and another perceptron on top can OR them together (see figure 11.7). We see that the first layer maps inputs from the (x_1, x_2) to the (z_1, z_2) space defined by the first-layer perceptrons. Note that both inputs, (0,0) and (1,1), are mapped to (0,0) in the (z_1, z_2) space, allowing linear separability in this second space.

Thus in the binary case, for every input combination where the output is 1, we define a hidden unit that checks for that particular conjunction of the input. The output layer then implements the disjunction. Note that this is just an existence proof, and such networks may not be practical as up to 2^d hidden units may be necessary when there are d inputs. Such an architecture implements table lookup and does not generalize.

We can extend this to the case where inputs are continuous to show that similarly, any arbitrary function with continuous input and outputs can be approximated with a multilayer perceptron. The proof of *universal approximation* is easy with two hidden layers: For every input case or region, that region can be delimited by hyperplanes on all sides using hidden units on the first hidden layer. A hidden unit in the second layer then ANDs them together to bound the region. We then set the weight of the connection from that hidden unit to the output unit equal to the desired function value. This gives a *piecewise constant approximation* of the function; it corresponds to ignoring all the terms in the Taylor expansion except the constant term. Its accuracy may be increased to the desired value by increasing the number of hidden units and placing a finer grid on the input. Note that no formal bounds are given on the number of hidden units required. This property just reassures us that there is a solution; it does not help us in any other way. It has been proven that an MLP with *one* hidden layer (with an arbitrary number of hidden units) can learn any nonlinear function of the input (Hornik, Stinchcombe, and White 1989).

UNIVERSAL APPROXIMATION

PIECEWISE CONSTANT APPROXIMATION

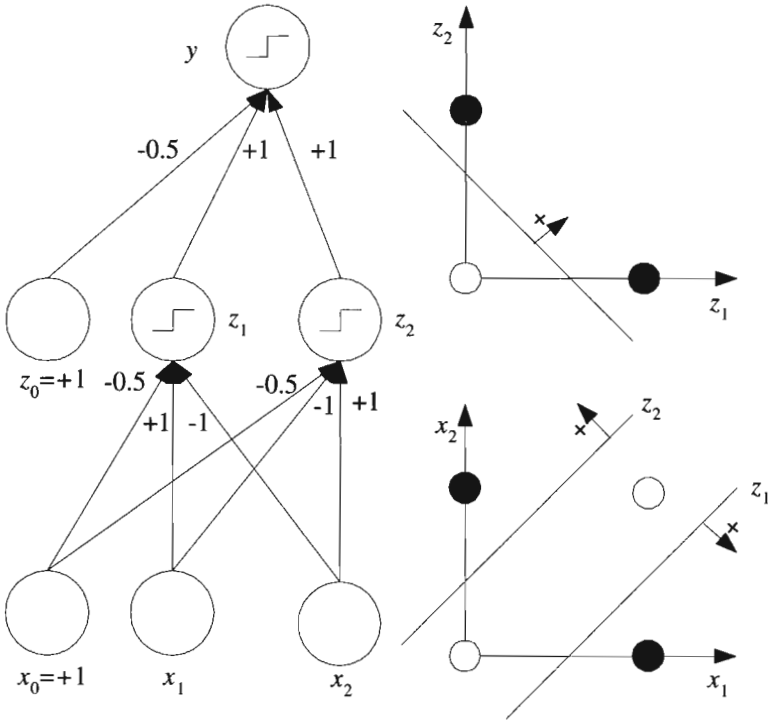

Figure 11.7 The multilayer perceptron that solves the XOR problem. The hidden units and the output have the threshold activation function with threshold at 0.

11.7 Backpropagation Algorithm

Training a multilayer perceptron is the same as training a perceptron; the only difference is that now the output is a nonlinear function of the input thanks to the nonlinear basis function in the hidden units. Considering the hidden units as inputs, the second layer is a perceptron and we already know how to update the parameters, v_{ij}, in this case, given the inputs h_j. For the first layer weights, w_{hj}, we use the chain rule to calculate the gradient:

$$\frac{\partial E}{\partial w_{hj}} = \frac{\partial E}{\partial y_i}\frac{\partial y_i}{\partial z_h}\frac{\partial z_h}{\partial w_{hj}}$$

BACKPROPAGATION

It is as if the error propagates from the output y back to the inputs and hence the name *backpropagation* was coined (Rumelhart, Hinton, and Williams 1986a).

11.7.1 Nonlinear Regression

Let us first take the case of nonlinear regression (with a single output) calculated as

$$y^t = \sum_{h=1}^{H} v_h z_h^t + v_0 \tag{11.13}$$

with z_h computed by equation 11.11. The error function over the whole sample in regression is

$$E(\mathbf{W}, \mathbf{v}|\mathcal{X}) = \frac{1}{2}\sum_t (r^t - y^t)^2 \tag{11.14}$$

The second layer is a perceptron with hidden units as the inputs, and we use the least-squares rule to update the second-layer weights:

$$\Delta v_h = \eta \sum_t (r^t - y^t) z_h^t \tag{11.15}$$

The first layer are also perceptrons with the hidden units as the output units but in updating the first-layer weights, we cannot use the least-squares rule directly as we do not have a desired output specified for the hidden units. This is where the chain rule comes into play. We write

$$\begin{aligned}
\Delta w_{hj} &= -\eta \frac{\partial E}{\partial w_{hj}} \\
&= -\eta \sum_t \frac{\partial E^t}{\partial y^t} \frac{\partial y^t}{\partial z_h^t} \frac{\partial z_h^t}{\partial w_{hj}} \\
&= -\eta \sum_t \underbrace{-(r^t - y^t)}_{\partial E^t/\partial y^t} \underbrace{v_h}_{\partial y^t/\partial z_h^t} \underbrace{z_h^t(1 - z_h^t)x_j^t}_{\partial z_h^t/\partial w_{hj}} \\
&= \eta \sum_t (r^t - y^t) v_h z_h^t (1 - z_h^t) x_j^t \qquad (11.16)
\end{aligned}$$

The product of the first two terms $(r^t - y^t)v_h$ acts like the error term for hidden unit h. This error is *backpropagated* from the error to the hidden unit. $(r^t - y^t)$ is the error in the output, weighted by the "responsibility" of the hidden unit as given by its weight v_h. In the third term, $z_h(1 - z_h)$

is the derivative of the sigmoid and x_j^t is the derivative of the weighted sum with respect to the weight w_{hj}. Note that the change in the first-layer weight, Δw_{hj}, makes use of the second-layer weight, v_h. Therefore, we should calculate the changes in both layers and update the first-layer weights, making use of the *old* value of the second-layer weights, then update the second-layer weights.

Weights, w_{hj}, v_h are started from small random values initially, for example, in the range $[-0.01, 0.01]$, so as not to saturate the sigmoids. It is also a good idea to normalize the inputs so that they all have 0 mean and unit variance and have the same scale, since we use a single η parameter.

With the learning equations given here, for each pattern, we compute the direction in which each parameter needs be changed and the magnitude of this change. In *batch learning*, we accumulate these changes over all patterns and make the change once after a complete pass over the whole training set is made, as shown in the previous update equations. A complete pass over all the patterns in the training set is called an *epoch*. It is also possible to have online learning, by updating the weights after each pattern, thereby implementing stochastic gradient descent. The learning factor, η, should be chosen smaller in this case and patterns should be scanned in a random order. Online learning converges faster because there may be similar patterns in the dataset, and the stochasticity has an effect like adding noise and may help escape local minima.

BATCH LEARNING

EPOCH

An example of training a multilayer perceptron for regression is shown in figure 11.8. As training continues, the MLP fit gets closer to the underlying function and error decreases (see figure 11.9). Figure 11.10 shows how the MLP fit is formed as a sum of the outputs of the hidden units.

It is also possible to have multiple output units, in which case a number of regression problems are learned at the same time. We have

$$y_i^t = \sum_{h=1}^{H} v_{ih} z_h^t + v_{i0} \tag{11.17}$$

and the error is

$$E(\mathbf{W}, \mathbf{V} | \mathcal{X}) = \frac{1}{2} \sum_t \sum_i (r_i^t - y_i^t)^2 \tag{11.18}$$

The batch update rules are then

$$\Delta v_{ih} = \eta \sum_t (r_i^t - y_i^t) z_h^t \tag{11.19}$$

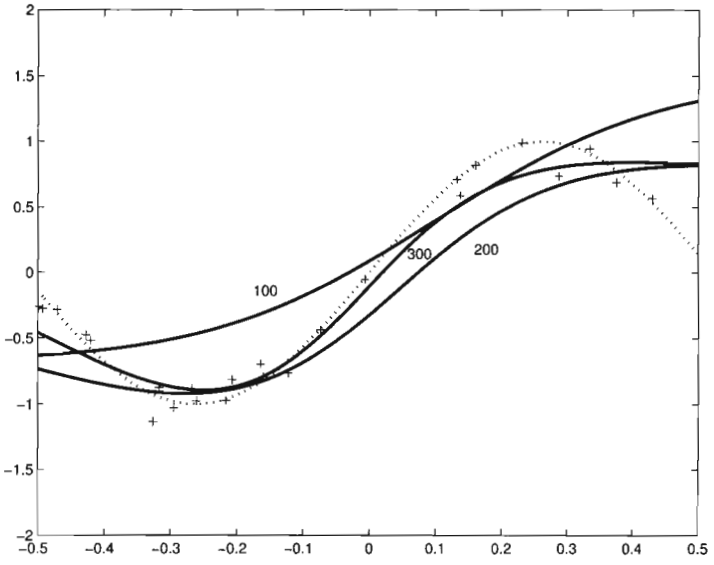

Figure 11.8 Sample training data shown as '+', where $x^t \sim U(-0.5, 0.5)$, and $y^t = f(x^t) + \mathcal{N}(0, 0.1)$. $f(x) = \sin(6x)$ is shown by a dashed line. The evolution of the fit of an MLP with two hidden units after 100, 200, and 300 epochs is drawn.

$$\Delta w_{hj} = \eta \sum_t \left[\sum_i (r_i^t - y_i^t) v_{ih} \right] z_h^t (1 - z_h^t) x_j^t \tag{11.20}$$

$\sum_i (r_i^t - y_i^t) v_{ih}$ is the accumulated backpropagated error of hidden unit h from all output units. Pseudocode is given in figure 11.11. Note that in this case, all output units share the same hidden units and thus use the same hidden representation. An alternative is to train separate multilayer perceptrons for the separate regression problems, each with its own separate hidden units.

11.7.2 Two-Class Discrimination

When there are two classes, one output unit suffices:

$$y^t = \text{sigmoid}\left(\sum_{h=1}^{H} v_h z_h^t + v_0 \right) \tag{11.21}$$

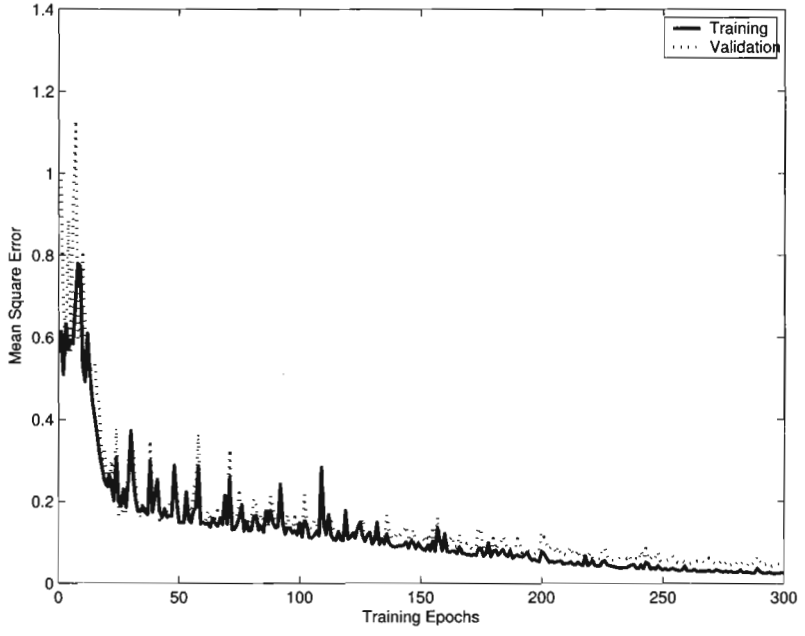

Figure 11.9 The mean square error on training and validation sets as a function of training epochs.

which approximates $P(C_1|\mathbf{x}^t)$ and $\hat{P}(C_2|\mathbf{x}^t) \equiv 1 - y^t$. We remember from section 10.7 that the error function in this case is

$$E(\mathbf{W}, \mathbf{v}|\mathcal{X}) = -\sum_t r^t \log y^t + (1 - r^t) \log(1 - y^t) \tag{11.22}$$

The update equations implementing gradient descent are

$$\Delta v_h = \eta \sum_t (r^t - y^t) z_h^t \tag{11.23}$$

$$\Delta w_{hj} = \eta \sum_t (r^t - y^t) v_h z_h^t (1 - z_h^t) x_j^t \tag{11.24}$$

As in the simple perceptron, the update equations for regression and classification are identical (which does not mean that the values are).

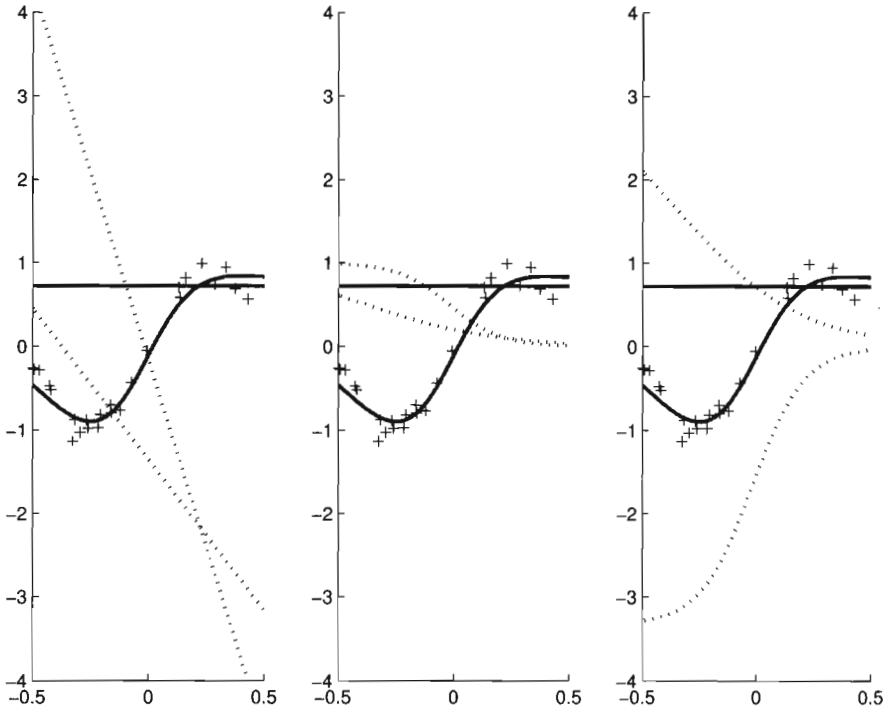

Figure 11.10 (a) The hyperplanes of the hidden unit weights on the first layer, (b) hidden unit outputs, and (c) hidden unit outputs multiplied by the weights on the second layer. Two sigmoid hidden units slightly displaced, one multiplied by a negative weight, when added, implement a bump. With more hidden units, a better approximation is attained (see figure 11.12).

11.7.3 Multiclass Discrimination

In a $(K > 2)$-class classification problem, there are K outputs

$$o_i^t = \sum_{h=1}^{H} v_{ih} z_h^t + v_{i0} \tag{11.25}$$

and we use softmax to indicate the dependency between classes, namely, they are mutually exclusive and exhaustive:

$$y_i^t = \frac{\exp o_i^t}{\sum_k \exp o_k^t} \tag{11.26}$$

```

        For i = 1, ..., K
            Δv_i = η(r_i^t − y_i^t) z
        For h = 1, ..., H
            Δw_h = η(Σ_i (r_i^t − y_i^t) v_ih) z_h (1 − z_h) x^t
        For i = 1, ..., K
            v_i ← v_i + Δv_i
        For h = 1, ..., H
            w_h ← w_h + Δw_h
Until convergence
```

Figure 11.11 Backpropagation algorithm for training a multilayer perceptron for regression with K outputs. This code can easily be adapted for two-class classification (by setting a single sigmoid output) and to $K > 2$ classification (by using softmax outputs).

where y_i approximates $P(C_i|\mathbf{x}^t)$. The error function is

$$E(\mathbf{W}, \mathbf{V}|\mathcal{X}) = -\sum_t \sum_i r_i^t \log y_i^t \tag{11.27}$$

and we get the update equations using gradient descent:

$$\Delta v_{ih} = \eta \sum_t (r_i^t - y_i^t) z_h^t \tag{11.28}$$

$$\Delta w_{hj} = \eta \sum_t \left[\sum_i (r_i^t - y_i^t) v_{ih} \right] z_h^t (1 - z_h^t) x_j^t \tag{11.29}$$

Richard and Lippmann (1991) have shown that given a network of enough complexity and sufficient training data, a suitably trained multilayer perceptron estimates posterior probabilities.

11.7.4 Multiple Hidden Layers

As we saw before, it is possible to have multiple hidden layers each with its own weights and applying the sigmoid function to its weighted sum. For regression, let us say, if we have a multilayer perceptron with two hidden layers, we write

$$z_{1h} = \text{sigmoid}(\mathbf{w}_{1h}^T \mathbf{x}) = \sum_{j=1}^{d} w_{1hj} x_j + w_{1h0}, \; h = 1, \ldots, H_1$$

$$z_{2l} = \text{sigmoid}(\mathbf{w}_{2l}^T \mathbf{z}_1) = \sum_{h=0}^{H_1} w_{2lh} z_{1h} + w_{2l0}, \; l = 1, \ldots, H_2$$

$$y = \mathbf{v}^T \mathbf{z}_2 = \sum_{l=1}^{H_2} v_l z_{2l} + v_0$$

where $\mathbf{w}_{1h}$ and $\mathbf{w}_{2l}$ are the first- and second-layer weights, z_{1h} and z_{2h} are the units on the first and second hidden layers, and $\mathbf{v}$ are the third-layer weights. Training such a network is similar except that to train the first-layer weights, we need to backpropagate one more layer (exercise 5).

11.8 Training Procedures

11.8.1 Improving Convergence

Gradient descent has various advantages. It is simple. It is local, namely, the change in a weight uses only the values of the presynaptic and postsynaptic units and the error (suitably backpropagated). When online training is used, it does not need to store the training set and can adapt as the task to be learned changes. Because of these reasons, it can be (and is) implemented in hardware. But by itself, gradient descent converges slowly. When learning time is important, one can use more sophisticated optimization methods (Battiti 1992). Bishop (1995) discusses in detail the application of conjugate gradient and second-order methods to the training of multilayer perceptrons. However, there are two frequently used simple techniques that improve the performance of the gradient descent considerably, making gradient-based methods feasible in real applications.

Momentum

Let us say w_i is any weight in a multilayer perceptron in any layer, including the biases. At each parameter update, successive Δw_i^t values may be so different that large oscillations may occur and slow convergence. t is the time index that is the epoch number in batch learning and the iteration number in online learning. The idea is to take a running average by incorporating the previous update in the current change as if there is a *momentum* due to previous updates:

MOMENTUM

$$\Delta w_i^t = -\eta \frac{\partial E^t}{\partial w_i} + \alpha \Delta w_i^{t-1} \tag{11.30}$$

α is generally taken between 0.5 and 1.0. This approach is especially useful when online learning is used, where as a result we get an effect of averaging and smooth the trajectory during convergence. The disadvantage is that the past Δw_i^{t-1} values should be stored in extra memory.

Adaptive Learning Rate

In gradient descent, the learning factor η determines the magnitude of change to be made in the parameter. It is generally taken between 0.0 and 1.0, mostly less than or equal to 0.2. It can be made adaptive for faster convergence, where it is kept large when learning takes place and is decreased when learning slows down:

$$\Delta\eta = \begin{cases} +a & \text{if } E^{t+\tau} < E^t \\ -b\eta & \text{otherwise} \end{cases} \tag{11.31}$$

Thus we increase η by a constant amount if the error on the training set decreases and decrease it geometrically if it increases. Because E may oscillate from one epoch to another, it is a better idea to take the average of the past few epochs as E^t.

11.8.2 Overtraining

A multilayer perceptron with d inputs, H hidden units, and K outputs has $H(d+1)$ weights in the first layer and $K(H+1)$ weights in the second layer. Both the space and time complexity of an MLP is $\mathcal{O}(H \cdot (K+d))$. When e denotes the number of training epochs, training time complexity is $\mathcal{O}(e \cdot H \cdot (K+d))$.

In an application, d and K are predefined and H is the parameter that we play with to tune the complexity of the model. We know from previous chapters that an overcomplex model memorizes the noise in the training set and does not generalize to the validation set. For example, we have previously seen this phenomenon in the case of polynomial regression where we noticed that in the presence of noise or small samples, increasing the polynomial order leads to worse generalization. Similarly in an MLP, when the number of hidden units is large, the generalization accuracy deteriorates (see figure 11.12), and the bias/variance dilemma also holds for the MLP, as it does for any statistical estimator (Geman, Bienenstock, and Doursat 1992).

A similar behavior happens when training is continued too long: As more training epochs are made, the error on the training set decreases, but the error on the validation set starts to increase beyond a certain point (see figure 11.13). Remember that initially all the weights are close to 0 and thus have little effect. As training continues, the most important weights start moving away from 0 and are utilized. But if training is continued further on to get less and less error on the training set, almost all weights are updated away from 0 and effectively become parameters. Thus as training continues, it is as if new parameters are added to the system, increasing the complexity and leading to poor generalization. Learning should be stopped before too late to alleviate the problem of *overtraining*. The optimal point to stop training, and the optimal number of hidden units, is determined through cross-validation, which involves testing the network's performance on validation data unseen during training.

OVERTRAINING

Because of the nonlinearity, the error function has many minima and gradient descent converges to the nearest minimum. To be able to assess expected error, the same network is trained a number of times starting from different initial weight values, and the average of the validation error is computed.

11.8.3 Structuring the Network

In some applications, we may believe that the input has a local structure. For example, in vision we know that nearby pixels are correlated and there are local features like edges and corners; any object, for example, a handwritten digit, may be defined as a combination of such primitives. Similarly, in speech, locality is in time and inputs close in time can be

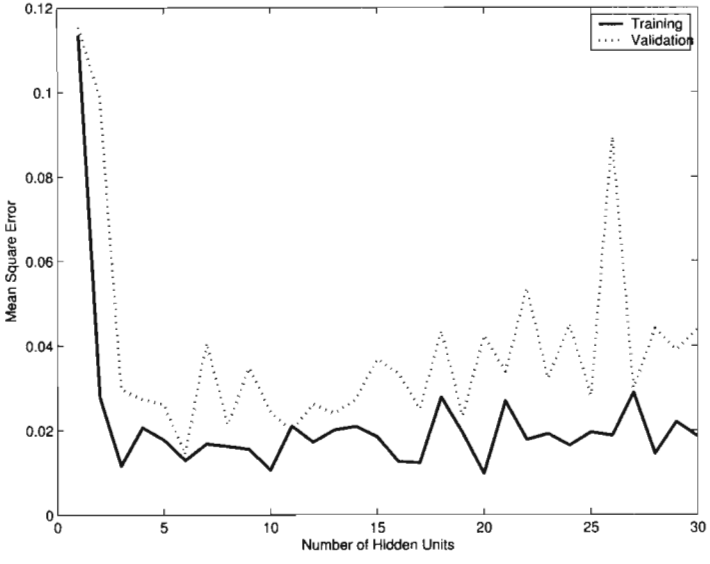

Figure 11.12 As complexity increases, training error is fixed but the validation error starts to increase and the network starts to overfit.

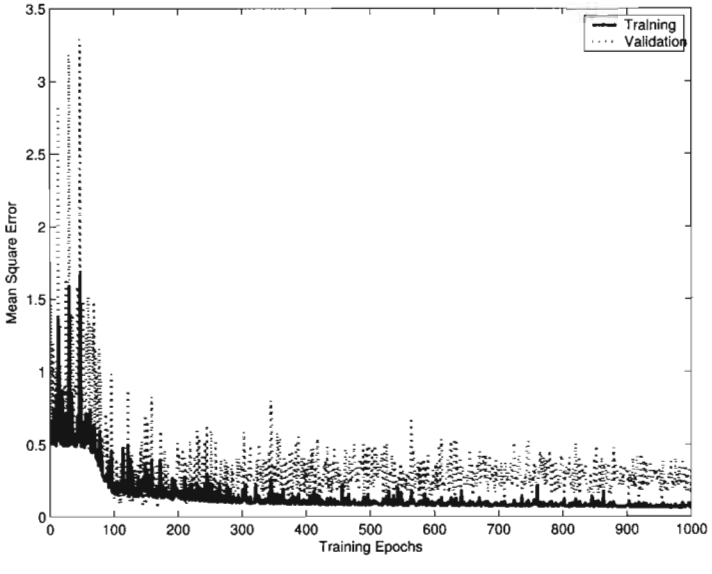

Figure 11.13 As training continues, the validation error starts to increase and the network starts to overfit.

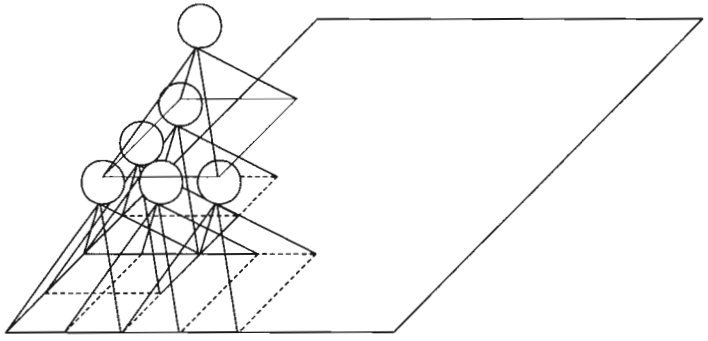

Figure 11.14 A structured MLP. Each unit is connected to a local group of units below it and checks for a particular feature—for example, edge, corner, and so forth—in vision. Only one hidden unit is shown for each region; typically there are many to check for different local features.

grouped as speech primitives. By combining these primitives, longer utterances, for example, speech phonemes, may be defined. In such a case when designing the MLP, hidden units are not connected to all input units because not all inputs are correlated. Instead, we define hidden units that define a window over the input space and are connected to only a small local subset of the inputs. This decreases the number of connections and therefore the number of free parameters (Le Cun et al. 1989).

We can repeat this in successive layers where each layer is connected to a small number of local units below and checks for a more complicated feature by combining the features below in a larger part of the input space until we get to the output layer (see figure 11.14). For example, the input may be pixels. By looking at pixels, the first hidden layer units may learn to check for edges of various orientations. Then by combining edges, the second hidden layer units can learn to check for combinations of edges—for example, arcs, corners, line ends—and then combining them in upper layers, the units can look for semi-circles, rectangles, or in the case of a face recognition application, eyes, mouth, and so forth. This is the example of a *hierarchical cone* where features get more complex, abstract, and fewer in number as we go up the network until we get to classes.

HIERARCHICAL CONE

In such a case, we can further reduce the number of parameters by *weight sharing.* Taking the example of visual recognition again, we can

WEIGHT SHARING

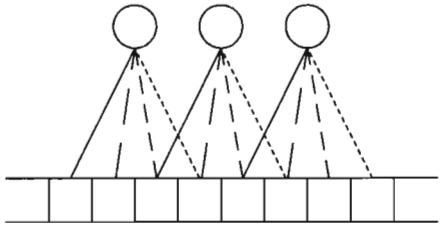

Figure 11.15 In weight sharing, different units have connections to different inputs but share the same weight value (denoted by line type). Only one set of units is shown; there should be multiple sets of units, each checking for different features.

see that when we look for features like oriented edges, they may be present in different parts of the input space. So instead of defining independent hidden units learning different features in different parts of the input space, we can have copies of the same hidden units looking at different parts of the input space (see figure 11.15). During learning, we calculate the gradients by taking different inputs, then we average these up and make a single update. This implies a single parameter that defines the weight on multiple connections. Also, because the update on a weight is based on gradients for several inputs, it as if the training set is effectively multiplied.

11.8.4 Hints

The knowledge of local structure allows us to prestructure the multilayer network and with weight sharing, it has fewer parameters. The alternative of an MLP with completely connected layers has no such structure and is more difficult to train. Knowledge of any sort related to the application should be built into the network structure whenever possible.

HINTS

These are called *hints* (Abu-Mostafa 1995) and are the properties of the target function that are known to us independent of the training examples.

In image recognition, there are invariance hints: The identity of an object does not change when it is rotated, translated, or scaled (see figure 11.16). Hints are auxiliary information that can be used to guide the learning process and are especially useful when the training set is limited. There are different ways in which hints can be used:

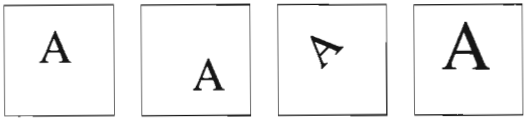

Figure 11.16 The identity of the object does not change when it is translated, rotated, or scaled. Note that this may not always be true, or may be true up to a point: 'b' and 'q' are rotated versions of each other. These are hints that can be incorporated into the learning process to make learning easier.

VIRTUAL EXAMPLES

1. Hints can be used to create *virtual examples.* For example, knowing that the object is invariant to scale, from a given training example, we can generate multiple copies at different scales and add them to the training set with the same label. This has the advantage that we increase the training set and do not need to modify the learner in any way. The problem may be that too many examples may be needed for the learner to learn the invariance.

2. The invariance may be implemented as a preprocessing stage. For example, optical character readers have a preprocessing stage where the input character image is centered and normalized for size and slant. This is the easiest solution, when it is possible.

3. The hint may be incorporated into the network structure. Local structure and weight sharing, which we saw in section 11.8.3, is one example where we get invariance to small translations and rotations.

4. The hint may also be incorporated by modifying the error function. Let us say we know that $\boldsymbol{x}$ and $\boldsymbol{x}'$ are the same from the application's point of view, where $\boldsymbol{x}'$ may be a "virtual example" of $\boldsymbol{x}$. That is, $f(\boldsymbol{x}) = f(\boldsymbol{x}')$, when $f(\boldsymbol{x})$ is the function we would like to approximate. Let us denote by $g(\boldsymbol{x}|\theta)$, our approximation function, for example, an MLP where θ are its weights. Then, for all such pairs $(\boldsymbol{x}, \boldsymbol{x}')$, we define the penalty function

$$E_h = [g(\boldsymbol{x}|\theta) - g(\boldsymbol{x}'|\theta)]^2$$

and add it as an extra term to the usual error function:

$$E' = E + \lambda_h \cdot E_h$$

This is a penalty term penalizing the cases where our predictions do not obey the hint, and λ_h is the weight of such a penalty (Abu-Mostafa 1995).

Another example is the approximation hint: Let us say that for x, we do not know the exact value, $f(x)$, but we know that it is in the interval, $[a_x, b_x]$. Then our added penalty term is

$$E_h = \begin{cases} 0 & \text{if } g(x|\theta) \in [a_x, b_x] \\ (g(x) - a_x)^2 & \text{if } g(x|\theta) < a_x \\ (g(x) - b_x)^2 & \text{if } g(x|\theta) > b_x \end{cases}$$

This is similar to the error function used in support vector regression (section 10.9.4), which tolerates small approximation errors.

TANGENT PROP

Still another example is the *tangent prop* (Simard et al. 1992) where the transformation against which we are defining the hint, for example, rotation by an angle, is modeled by a function. The usual error function is modified (by adding another term) so as to allow parameters to move along this line of transformation without changing the error.

11.9 Tuning the Network Size

Previously we saw that when the network is too large and has too many free parameters, generalization may not be well. To find the optimal network size, the most common approach is to try many different architectures, train them all on the training set, and choose the one that generalizes best to the validation set. Another approach is to incorporate this *structural adaptation* into the learning algorithm. There are two ways this can be done:

STRUCTURAL ADAPTATION

1. In the *destructive* approach, we start with a large network and gradually remove units and/or connections that are not necessary.
2. In the *constructive* approach, we start with a small network and gradually add units and/or connections to improve performance.

WEIGHT DECAY

One destructive method is *weight decay* where the idea is to remove unnecessary connections. Ideally to be able to determine whether a unit or connection is necessary, we need to train once with and once without and

check the difference in error on a separate validation set. This is costly since it should be done for all combinations of such units/connections.

Given that a connection is not used if its weight is 0, we give each connection a tendency to decay to 0 so that it disappears unless it is reinforced explicitly to decrease error. For any weight w_i in the network, we use the update rule:

$$\Delta w_i = -\eta \frac{\partial E}{\partial w_i} - \lambda w_i \tag{11.32}$$

This is equivalent to doing gradient descent on the error function with an added penalty term, penalizing networks with many nonzero weights:

$$E' = E + \frac{\lambda}{2} \sum_i w_i^2 \tag{11.33}$$

Simpler networks are better generalizers is a hint that we implement by adding a penalty term. Note that we are not saying that simple networks are always better than large networks; we are saying that if we have two networks that have the same training error, the simpler one—namely, the one with fewer weights—has a higher probability of better generalizing to the validation set.

The effect of the second term in equation 11.32 is like that of a spring that pulls each weight to 0. Starting from a value close to 0, unless the actual error gradient is large and causes an update, due to the second term, the weight will gradually decay to 0. λ is the parameter that determines the relative importances of the error on the training set and the complexity due to nonzero parameters and thus determines the speed of decay: With large λ, weights will be pulled to 0 no matter what the training error is; with small λ, there is not much penalty for nonzero weights. λ is fine-tuned using cross-validation.

Instead of starting from a large network and *pruning* unnecessary connections or units, one can start from a small network and add units and associated connections should the need arise (figure 11.17). In *dynamic node creation* (Ash 1989), an MLP with one hidden layer with one hidden unit is trained and after convergence, if the error is still high, another hidden unit is added. The incoming weights of the newly added unit and its outgoing weight are initialized randomly and trained with the previously existing weights that are not reinitialized and continue from their previous values.

DYNAMIC NODE CREATION

In *cascade correlation* (Fahlman and Lebiere 1990), each added unit

CASCADE CORRELATION

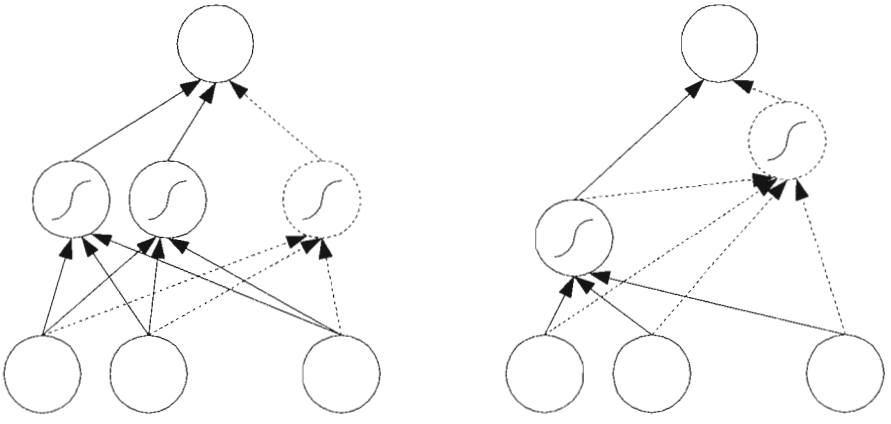

Figure 11.17 Two examples of constructive algorithms: Dynamic node creation adds a unit to an existing layer. Cascade correlation adds each unit as new hidden layer connected to all the previous layers. Dashed lines denote the newly added unit/connections. Bias units/weights are omitted for clarity.

is a new hidden unit in another hidden layer. Every hidden layer has only one unit that is connected to all of the hidden units preceding it and the inputs. The previously existing weights are frozen and are not trained; only the incoming and outgoing weights of the newly added unit are trained.

Dynamic node creation adds a new hidden unit to an existing hidden layer and never adds another hidden layer. Cascade correlation always adds a new hidden layer with a single unit. The ideal constructive method should be able to decide when to introduce a new hidden layer and when to add a unit to an existing layer. This is an open research problem.

Incremental algorithms are interesting because they correspond to modifying not only the parameters but also the model structure during learning. An analogy would be a setting in polynomial regression where high-order terms are added/removed during training automatically, fitting model complexity to data complexity. As the cost of computation gets lower, such automatic model selection should be a part of the learning process done automatically without any user interference.

11.10 Bayesian View of Learning

The Bayesian approach in training neural networks considers the parameters, namely, connection weights, w_i, as random variables drawn from a prior distribution $p(w_i)$ and computes the posterior probability given the data

$$p(\mathbf{w}|\mathcal{X}) = \frac{p(\mathcal{X}|\mathbf{w})p(\mathbf{w})}{p(\mathcal{X})} \tag{11.34}$$

where $\mathbf{w}$ is the vector of all weights of the network. The MAP estimate $\hat{\mathbf{w}}$ is the mode of the posterior

$$\hat{\mathbf{w}}_{MAP} = \arg\max_{\mathbf{w}} \log p(\mathbf{w}|\mathcal{X}) \tag{11.35}$$

Taking the log of equation 11.34, we get

$$\log p(\mathbf{w}|\mathcal{X}) = \log p(\mathcal{X}|\mathbf{w}) + \log p(\mathbf{w}) + C$$

The first term on the right is the log likelihood, and the second is the log of the prior. If the weights are independent and the prior is taken as Gaussian, $\mathcal{N}(0, 1/2\lambda)$

$$p(\mathbf{w}) = \prod_i p(w_i) \text{ where } p(w_i) = c \cdot \exp\left[-\frac{w_i^2}{2(1/2\lambda)}\right] \tag{11.36}$$

the MAP estimate minimizes the augmented error function

$$E' = E + \lambda\|\mathbf{w}\|^2 \tag{11.37}$$

where E is the usual classification or regression error (negative log likelihood). This augmented error is exactly the error function we used in weight decay (equation 11.33). Using a large λ assumes small variability in parameters, puts a larger force on them to be close to 0, and takes the prior more into account than the data; if λ is small, then the allowed variability of the parameters is larger. This approach of removing unnecessary parameters is known as *ridge regression* in statistics.

RIDGE REGRESSION

REGULARIZATION

This is another example of *regularization* with a cost function, combining the fit to data and model complexity

$$\text{cost} = \text{data-misfit} + \lambda \cdot \text{complexity} \tag{11.38}$$

The use of Bayesian estimation in training multilayer perceptrons is treated in MacKay 1992a, b.

Empirically, it has been seen that after training, most of the weights of a multilayer perceptron are distributed normally around 0, justifying the use of weight decay. But this may not always be the case. Nowlan and Hinton (1992) proposed *soft weight sharing* where weights are drawn from a mixture of Gaussians, allowing them to form multiple clusters, not one. Also, these clusters may be centered anywhere and not necessarily at 0, and have variances that are modifiable. This changes the prior of equation 11.36 to a mixture of $M \geq 2$ Gaussians

SOFT WEIGHT SHARING

$$p(w_i) = \sum_{j=1}^{M} \alpha_j p_j(w_i) \tag{11.39}$$

where α_j are the priors and $p_j(w_i) \sim \mathcal{N}(m_j, s_j^2)$ are the component Gaussians. M is set by the user and α_j, m_j, s_j are learned from the data. Using such a prior and augmenting the error function with its log during training, the weights converge to decrease error and also are grouped automatically to increase the log prior.

11.11 Dimensionality Reduction

In a multilayer perceptron, if the number of hidden units is less than the number of inputs, the first layer performs a dimensionality reduction. The form of this reduction and the new space spanned by the hidden units depend on what the MLP is trained for. If the MLP is for classification with output units following the hidden layer, then the new space is defined and the mapping is learned to minimize classification error (see figure 11.18).

We can get an idea of what the MLP is doing by analyzing the weights. We know that the dot product is maximum when the two vectors are identical. So we can think of each hidden unit as defining a template in its incoming weights, and by analyzing these templates, we can extract knowledge from a trained MLP. If the inputs are normalized, weights tell us of their relative importance. Such analysis is not easy but gives us some insight as to what the MLP is doing and allows us to peek into the black box.

AUTOASSOCIATOR

An interesting architecture is the *autoassociator* (Cottrell, Munro, and Zipser 1987), which is an MLP architecture where there are as many outputs as there are inputs, and the required outputs are defined to be equal to the inputs (see figure 11.19). To be able to reproduce the inputs again

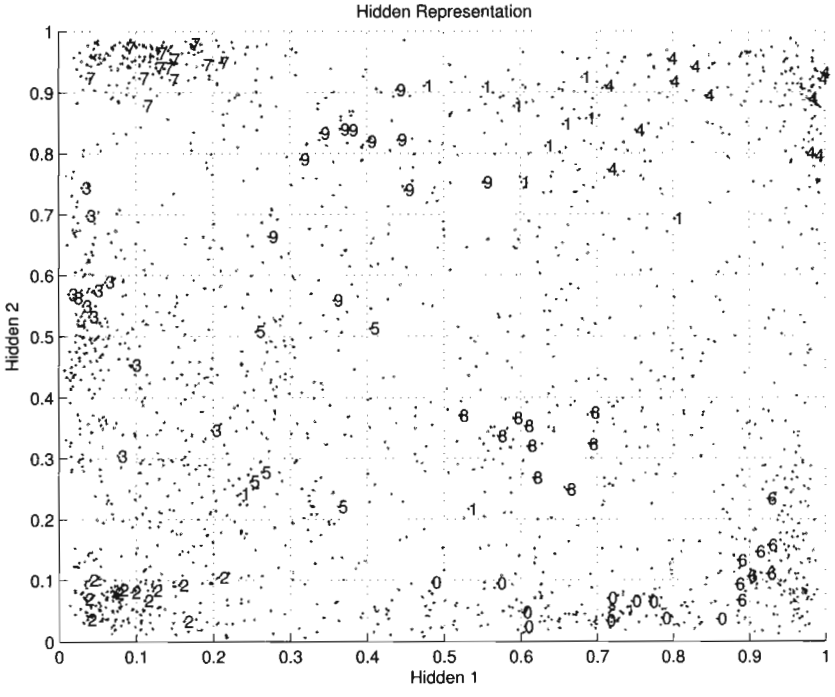

Figure 11.18 Optdigits data plotted in the space of the two hidden units of an MLP trained for classification. Only the labels of one hundred data points are shown. This MLP with sixty-four inputs, two hidden units, and ten outputs has 80 percent accuracy. Because of the sigmoid, hidden unit values are between 0 and 1 and classes are clustered around the corners. This plot can be compared with the plots in chapter 6, which are drawn using other dimensionality reduction methods on the same dataset.

at the output layer, the MLP is forced to find the best representation of the inputs in the hidden layer. When the number of hidden units is less than the number of inputs, this implies dimensionality reduction. Once the training is done, the first layer from the input to the hidden layer acts as an encoder, and the values of the hidden units make up the encoded representation. The second layer from the hidden units to the output units acts as a decoder, reconstructing the original signal from its encoded representation.

It has been shown (Bourlard and Kamp 1988) that an MLP with one

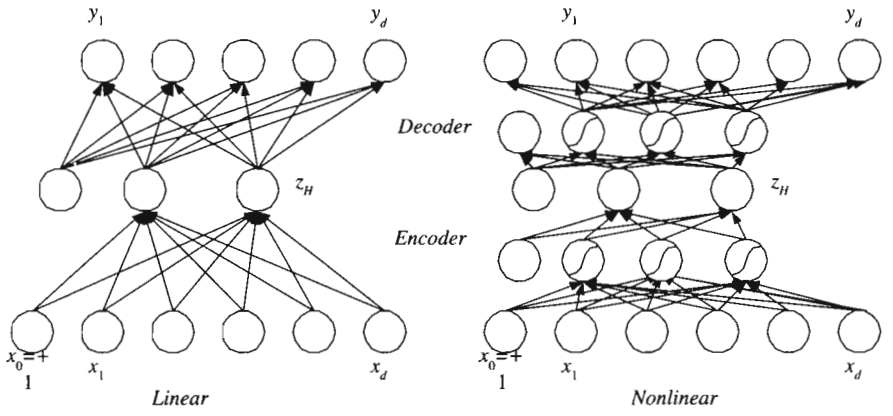

Figure 11.19 In the autoassociator, there are as many outputs as there are inputs and the desired outputs are the inputs. When the number of hidden units is less than the number of inputs, the MLP is trained to find the best coding of the inputs on the hidden units, performing dimensionality reduction. On the left, the first layer acts as an encoder and the second layer acts as the decoder. On the right, if the encoder and decoder are multilayer perceptrons with sigmoid hidden units, the network performs nonlinear dimensionality reduction.

hidden layer of units implements principal components analysis (section 6.3), except that the hidden unit weights are not the eigenvectors sorted in importance using the eigenvalues, but span the same space as the H principal eigenvectors. If the encoder and decoder are not one layer but multilayer perceptrons with sigmoid nonlinearity in the hidden units, the encoder implements nonlinear dimensionality reduction.

Another way to use an MLP for dimensionality reduction is through multidimensional scaling (section 6.5). Mao and Jain (1995) show how an MLP can be used to learn the *Sammon mapping*. Recalling equation 6.29, Sammon stress is defined as

SAMMON MAPPING

$$E(\theta|\mathcal{X}) = \sum_{r,s} \left[\frac{\|\boldsymbol{g}(\boldsymbol{x}^r|\theta) - \boldsymbol{g}(\boldsymbol{x}^s|\theta)\| - \|\boldsymbol{x}^r - \boldsymbol{x}^s\|}{\|\boldsymbol{x}^r - \boldsymbol{x}^s\|} \right]^2 \tag{11.40}$$

An MLP with d inputs, H hidden units, and $k < d$ output units is used to implement $g(\boldsymbol{x}|\theta)$, mapping the d-dimensional input to a k-dimensional vector, where θ corresponds to the weights of the MLP. Given a dataset of $\mathcal{X} = \{\boldsymbol{x}^t\}_t$, we can use gradient descent to minimize the Sammon stress directly to learn the MLP, namely, $g(\boldsymbol{x}|\theta)$, such that the distances be-

tween the k-dimensional representations are as close as possible to the distances in the original space.

11.12 Learning Time

Until now, we have been concerned with cases where the input is fed once, all together. In some applications, the input is temporal where we need to learn a temporal sequence. In others, the output may also change in time. Examples are

- *Sequence recognition.* This is the assignment of a given sequence to one of several classes. Speech recognition is one example where the input signal sequence is the spoken speech and the output is the code of the word spoken. That is, the input changes in time but the output does not.

- *Sequence reproduction.* Here, after seeing part of a given sequence, the system should predict the rest. Time-series prediction is one example where the input is given but the output changes.

- *Temporal association.* This is the most general case where a particular output sequence is given as output after a specific input sequence. The input and output sequences may be different. Here both the input and the output change in time.

11.12.1 Time Delay Neural Networks

TIME DELAY NEURAL NETWORK

The easiest way to recognize a temporal sequence is by converting it to a spatial sequence. Then any method discussed up to this point can be utilized for classification. In a *time delay neural network* (Waibel et al. 1989), previous inputs are delayed in time so as to synchronize with the final input, and all are fed together as input to the system (see figure 11.20). Backpropagation can then be used to train the weights. To extract features local in time, one can have layers of structured connections and weight sharing to get translation invariance in time. The main restriction of this architecture is that the size of the time window we slide over the sequence should be fixed a priori.

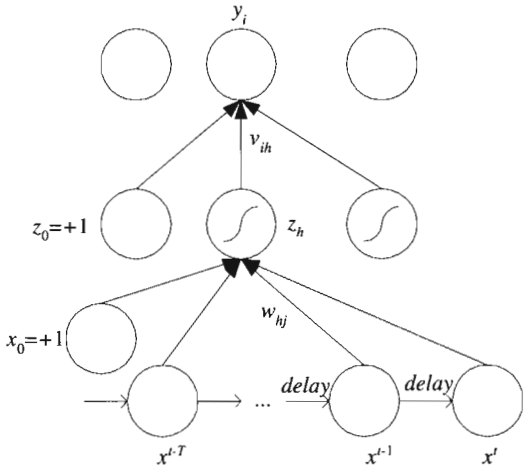

Figure 11.20 A time delay neural network. Inputs in a time window of length T are delayed in time until we can feed all T inputs as the input vector to the MLP.

11.12.2 Recurrent Networks

RECURRENT NETWORK

In a *recurrent network,* additional to the feedforward connections, units have self-connections or connections to units in the previous layers. This recurrency acts as a short-term memory and lets the network remember what happened in the past.

Most frequently, one uses a partially recurrent network where a limited number of recurrent connections are added to a multilayer perceptron (see figure 11.21). This combines the advantage of the nonlinear approximation ability of a multilayer perceptron with the temporal representation ability of the recurrency, and such a network can be used to implement any of the three temporal association tasks. It is also possible to have hidden units in the recurrent backward connections, these being known as *context units.* No formal results are known to determine how to choose the best architecture given a particular application.

UNFOLDING IN TIME

If the sequences have a small maximum length, then *unfolding in time* can be used to convert an arbitrary recurrent network to an equivalent feedforward network (see figure 11.22). A separate unit and connection is created for copies at different times. The resulting network can be trained with backpropagation with the additional requirement that all

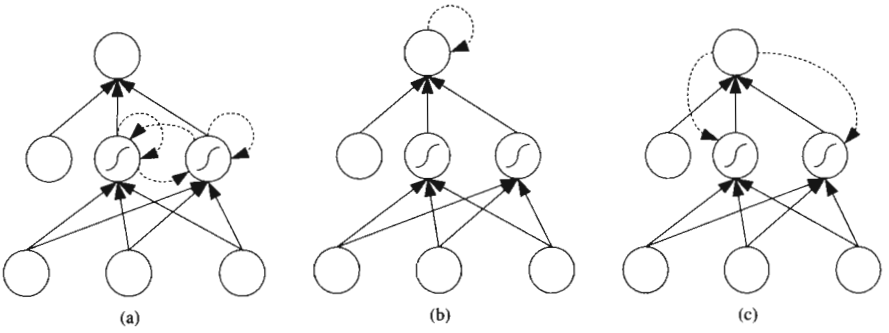

Figure 11.21 Examples of MLP with partial recurrency. Recurrent connections are shown with dashed lines: (a) self-connections in the hidden layer, (b) self-connections in the output layer, and (c) connections from the output to the hidden layer. Combinations of these are also possible.

copies of each connection should remain identical. The solution, as in weight sharing, is to sum up the different weight changes in time and change the weight by the average. This is called *backpropagation through time* (Rumelhart, Hinton, and Willams 1986b). The problem with this approach is the memory requirement if the length of the sequence is large. *Real time recurrent learning* (Williams and Zipser 1989) is an algorithm for training recurrent networks without unfolding and has the advantage that it can use sequences of arbitrary length.

BACKPROPAGATION THROUGH TIME

REAL TIME RECURRENT LEARNING

11.13 Notes

Research on artificial neural networks is as old as the digital computer. McCulloch and Pitts (1943) proposed the first mathematical model for the artificial neuron. Rosenblatt (1962) proposed the perceptron model and a learning algorithm in 1962. Minsky and Papert (1969) showed the limitation of single-layer perceptrons, for example, the XOR problem, and since there was no algorithm to train a multilayer perceptron with a hidden layer at that time, the work on artificial neural networks almost stopped except at a few places. The renaissance of neural networks came with the paper by Hopfield (1982). This was followed by the two-volume Parallel Distributed Processing (PDP) book written by the PDP Research Group (Rumelhart and McClelland 1986). It seems as though backpropagation

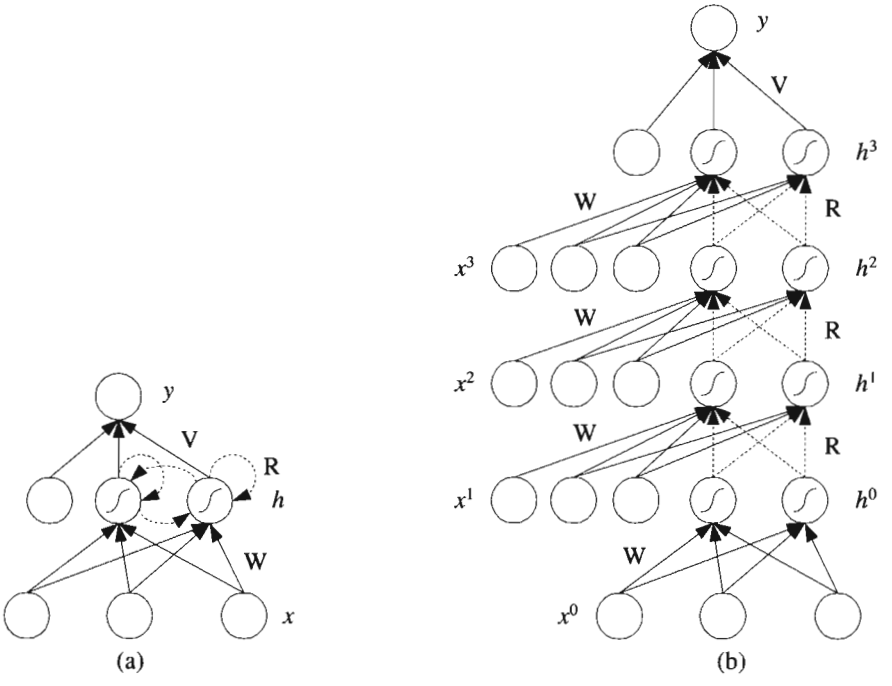

Figure 11.22 Backpropagation through time: (a) recurrent network and (b) its equivalent unfolded network that behaves identically in four steps.

was invented independently in several places almost at the same time and the limitation of a single-layer perceptron no longer held.

Starting in the mid-1980s, there has been a huge explosion of work on artificial neural network models from various disciplines: physics, statistics, psychology, cognitive science, neuroscience, and lingustics, not to mention computer science, electrical engineering, and adaptive control. Perhaps the most important contribution of research on artificial neural networks is this synergy that bridged various disciplines, especially statistics and engineering. It is thanks to this that the field of machine learning is now well-established.

The field is much more mature now; aims are more modest and better defined. One of the criticisms of backpropagation was that it was not biologically plausible! Though the term "neural network" is still widely used, it is generally understood that neural network models, for example,

multilayer perceptrons, are nonparametric estimators and that the best way to analyze them is by using statistical methods.

PROJECTION PURSUIT

For example, a statistical method similar to the multilayer perceptron is *projection pursuit* (Friedman and Stuetzle 1981), which is written as

$$y = \sum_{h=1}^{H} \phi_h(\mathbf{w}_h^T \mathbf{x})$$

the difference being that each "hidden unit" has its own separate function, $\phi_h(\cdot)$, though in an MLP, all are fixed to be sigmoid. In chapter 12, we will see another neural network structure, named radial basis functions, which uses the Gaussian function at the hidden units.

There are various textbooks on artificial neural networks: Hertz, Krogh, and Palmer 1991, the earliest, is still readable. Bishop 1995 has a pattern recognition emphasis and discusses in detail various optimization algorithms that can be used for training, as well as the Bayesian approach, generalizing weight decay. Ripley 1996 analyzes neural networks from a statistical perspective.

Artificial neural networks, for example, multilayer perceptrons, have various successful applications. In addition to their various successful applications in adaptive control, speech recognition, and vision, two are noteworthy: Tesauro's TD-Gammon program (Tesauro 1994) uses reinforcement learning (chapter 16) to train a multilayer perceptron and plays backgammon at a master level. Pomerleau's ALVINN is a neural network that autonomously drives a van up to 20 miles per hour after learning by observing a driver for five minutes (Pomerleau 1991).

11.14 Exercises

1. Show the perceptron that calculates NOT of its input.
2. Show the perceptron that calculates NAND of its two inputs.
3. Show the perceptron that calculates the parity of its three inputs.
4. Derive the update equations when the hidden units use tanh, instead of the sigmoid. Use the fact that $\tanh' = (1 - \tanh^2)$.
5. Derive the update equations for an MLP with two hidden layers.
6. Parity is cyclic shift invariant, for example, "0101" and "1010" have the same parity. Propose a multilayer perceptron to learn the parity function using this hint.

7. In cascade correlation, what are the advantages of freezing the previously existing weights?
8. Derive the update equations for an MLP implementing Sammon mapping that minimizes Sammon stress (equation 11.40).

12 *Local Models*

We continue our discussion of multilayer neural networks with models where the first layer contains locally receptive units that respond to instances in a localized region of the input space. The second layer on top learns the regression or classification function for these local regions. We discuss learning methods for finding the local regions of importance as well as the models responsible in there.

12.1 Introduction

ONE WAY to do function approximation is to divide the input space into local patches and learn a separate fit in each local patch. In chapter 7, we discussed statistical methods for clustering that allowed us to group input instances and model the input distribution. Competitive methods are neural network methods for online clustering. In this chapter, we discuss the online version of k-means, as well as two neural network extensions, adaptive resonance theory (ART), and the self-organizing map (SOM).

We then discuss how supervised learning is implemented once the inputs are localized. If the fit in a local patch is constant, then the technique is named the radial basis function (RBF) network; if it is a linear function of the input, it is called the mixture of experts (MoE). We discuss both regression and classification, and also compare this approach with MLP, which we discussed in chapter 11.

12.2 Competitive Learning

In chapter 7, we used the semiparametric Gaussian mixture density, which assumes that the input comes from one of k Gaussian sources. In this section, we make the same assumption that there are k groups (or clusters) in the data, but our approach is not probabilistic in that we do not enforce a parametric model for the sources. Another difference is that the learning methods we propose are online: We do not have the whole sample at hand during training; we receive instances one by one and update model parameters as we get them. The term *competitive learning* is used because it is as if these groups, or rather the units representing these groups, compete among themselves to be the one responsible for representing an instance. The model is also called *winner-take-all;* it is as if one group wins and gets updated, and the others are not updated at all.

COMPETITIVE LEARNING

WINNER-TAKE-ALL

These methods can be used by themselves for online clustering, as opposed to the batch methods discussed in chapter 7. An online method has the usual advantages that (1) we do not need extra memory to store the whole training set; (2) updates at each step are simple to implement, for example, in hardware; and (3) the input distribution may change in time and the model adapts itself to these changes automatically. If we were to use a batch algorithm, we would need to collect a new sample and run the batch method from scratch over the whole sample.

Starting in section 12.3, we will also discuss how such an approach can be followed by a supervised method to learn regression or classification problems. This will be a two-stage system that can be implemented by a two-layer network, where the first stage (-layer) models the input density and finds the responsible local model, and the second stage is that of the local model generating the final output.

12.2.1 Online k-Means

In equation 7.3, we defined the reconstruction error as

$$E(\{\mathbf{m}_i\}_{i=1}^k | \mathcal{X}) = \frac{1}{2}\sum_t \sum_i b_i^t \|\mathbf{x}^t - \mathbf{m}_i\|^2 \tag{12.1}$$

where

$$b_i^t = \begin{cases} 1 & \text{if } \|\mathbf{x}^t - \mathbf{m}_i\| = \min_l \|\mathbf{x}^t - \mathbf{m}_l\| \\ 0 & \text{otherwise} \end{cases} \tag{12.2}$$

$\mathcal{X} = \{\boldsymbol{x}^t\}_t$ is the sample and $\boldsymbol{m}_i, i = 1, \ldots, k$ are the cluster centers. b_i^t is 1 if $\boldsymbol{m}_i$ is the closest center to $\boldsymbol{x}^t$ in Euclidean distance. It is as if all $\boldsymbol{m}_l, l = 1, \ldots, k$ compete and $\boldsymbol{m}_i$ wins the competition because it is the closest.

The batch algorithm, k-means, updates the centers as

$$\boldsymbol{m}_i = \frac{\sum_t b_i^t \boldsymbol{x}^t}{\sum_t b_i^t} \tag{12.3}$$

which minimizes equation 12.1, once the winners are chosen using equation 12.2. As we saw before, these two steps of calculation of b_i^t and update of $\boldsymbol{m}_i$ are iterated until convergence.

ONLINE k-MEANS

We can obtain *online k-means* by doing stochastic gradient descent, considering the instances one by one, and doing a small update at each step, not forgetting the effect of the previous updates. The reconstruction error for a single instance is

$$E^t(\{\boldsymbol{m}_i\}_{i=1}^k | \boldsymbol{x}^t) = \frac{1}{2}\sum_i b_i^t \|\boldsymbol{x}^t - \boldsymbol{m}_i\|^2 = \frac{1}{2}\sum_i \sum_{j=1}^d b_i^t (x_j^t - m_{ij})^2 \tag{12.4}$$

where b_i^t is defined as in equation 12.2. Using gradient descent on this, we get the following update rule for each instance $\boldsymbol{x}^t$:

$$\Delta m_{ij} = -\eta \frac{\partial E^t}{\partial m_{ij}} = \eta b_i^t (x_j^t - m_{ij}) \tag{12.5}$$

This moves the closest center (for which $b_i^t = 1$) toward the input by a factor given by η. The other centers have their $b_l^t, l \neq i$ equal to 0 and are not updated (see figure 12.1). A batch procedure can also be defined by summing up equation 12.5 over all t. Like in any gradient descent procedure, a momentum term can also be added. For convergence, η is gradually decreased to 0. But this implies the *stability-plasticity dilemma:* If η is decreased toward 0, the network becomes stable but we lose adaptivity to novel patterns that may occur in time because updates become too small. If we keep η large, $\boldsymbol{m}_i$ may oscillate.

STABILITY-PLASTICITY DILEMMA

The pseudocode of online k-means is given in figure 12.2. This is the online version of the batch algorithm given in figure 7.3.

The competitive network can be implemented as a one-layer recurrent network as shown in figure 12.3. The input layer contains the input vector $\boldsymbol{x}$; note that there is no bias unit. The values of the output units are the b_i and they are perceptrons:

$$b_i = \boldsymbol{m}_i^T \boldsymbol{x} \tag{12.6}$$

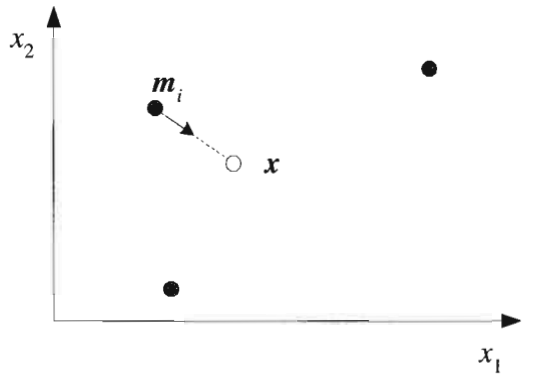

Figure 12.1 Shaded circles are the centers and the empty circle is the input instance. The online version of k-means moves the closest center along the direction of $(\boldsymbol{x} - \boldsymbol{m}_i)$ by a factor specified by η.

LATERAL INHIBITION

Then we need to choose the maximum of the b_i and set it equal to 1, and set the others, $b_l, l \neq i$ to 0. If we would like to do everything purely neural, that is, using a network of concurrently operating processing units, the choosing of the maximum can be implemented through *lateral inhibition.* As shown in figure 12.3, each unit has an excitatory recurrent connection (i.e., with a positive weight) to itself, and inhibitory recurrent connections (i.e., with negative weights) to the other output units. With an appropriate nonlinear activation function and positive and negative recurrent weight values, such a network, after some iterations, converges to a state where the maximum becomes 1 and all others become 0 (Grossberg 1980; Feldman and Ballard 1982).

The dot product used in equation 12.6 is a similarity measure, and we saw in section 5.5 (equation 5.26) that if $\boldsymbol{m}_i$ have the same norm, then the unit with the minimum Euclidean distance, $\|\boldsymbol{m}_i - \boldsymbol{x}\|$, is the same as the one with the maximum dot product, $\boldsymbol{m}_i^T \boldsymbol{x}$.

Here, and later when we discuss other competitive methods, we use the Euclidean distance, but we should keep in mind that using the Euclidean distance implies that all input attributes have the same variance and that they are not correlated. If this is not the case, this should be reflected in the distance measure, that is, by using the Mahalanobis distance, or suitable normalization should be done, for example, by PCA, at

Initialize $\mathbf{m}_i, i = 1, \ldots, k$, for example, to k random $\mathbf{x}^t$
Repeat
  For all $\mathbf{x}^t \in \mathcal{X}$ in random order
    $i \leftarrow \arg\min_j \|\mathbf{x}^t - \mathbf{m}_j\|$
    $\mathbf{m}_i \leftarrow \mathbf{m}_i + \eta(\mathbf{x}^t - \mathbf{m}_j)$
Until $\mathbf{m}_i$ converge

Figure 12.2 Online k-means algorithm. The batch version is given in figure 7.3.

a preprocessing stage before the Euclidean distance is used.

We can rewrite equation 12.5 as

$$\Delta m_{ij}^t = \eta b_i^t x_j^t - \eta b_i^t m_{ij} \tag{12.7}$$

Let us remember that m_{ij} is the weight of the connection from x_j to b_i. An update of the form, as we see in the first term

$$\Delta m_{ij}^t = \eta b_i^t x_j^t \tag{12.8}$$

HEBBIAN LEARNING

is *Hebbian learning,* which defines the update as the product of the values of the presynaptic and postsynaptic units. It was proposed as a model for neural plasticity: A synapse becomes more important if the units before and after the connection fire simultaneously, indicating that they are correlated. However, with only Hebbian learning, the weights grow without bound ($x_j^t \geq 0$), and we need a second force to decrease the weights that are not updated. One possibility is to explicitly normalize the weights to have $\|\mathbf{m}_i\| = 1$; if $\Delta m_{ij} > 0$ and $\Delta m_{il} = 0, l \neq i$, once we normalize $\mathbf{m}_i$ to unit length, m_{il} decrease. Another possibility is to introduce a weight decay term (Oja 1982), and the second term of equation 12.7 can be seen as such. Hertz, Krogh, and Palmer (1991) discuss competitive networks and Hebbian learning in more detail and show, for example, how such networks can learn to do PCA. Mao and Jain (1995) discuss online algorithms for PCA and LDA.

As we saw in chapter 7, one problem is to avoid dead centers, namely, the ones that are there but are not effectively utilized. In the case of competitive networks, this corresponds to centers that never win the competition because they are initialized far away from any input. There are various ways we can avoid this:

1. We can initialize $\mathbf{m}_i$ by randomly chosen input instances, and make sure that they start from where there is data.

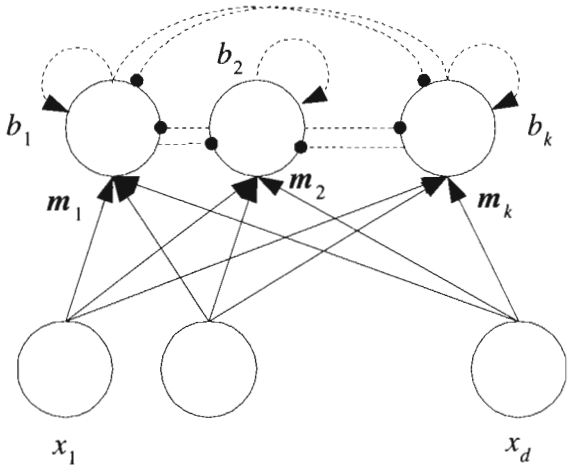

Figure 12.3 The winner-take-all competitive neural network, which is a network of k perceptrons with recurrent connections at the output. Dashed lines are recurrent connections, of which the ones that end with an arrow are excitatory and the ones that end with a circle are inhibitory. Each unit at the output reinforces its value and tries to suppress the other outputs. Under a suitable assignment of these recurrrent weights, the maximum suppresses all the others. This has the net effect that the one unit whose $\boldsymbol{m}_i$ is closest to $\boldsymbol{x}$ ends up with its b_i equal to 1 and all others, namely, $b_l, l \neq i$ are 0.

2. We can use a leader-cluster algorithm and add units one by one, always adding them at a place where they are needed. One example is the ART model, which we discuss in section 12.2.2.

3. When we update, we do not update only the center of the closest unit but some others as well. As they are updated, they also move toward the input, move gradually toward parts of the input space where there are inputs, and eventually win the competition. One example that we discuss in section 12.2.3 is SOM.

4. Another possibility is to introduce a *conscience* mechanism (DeSieno 1988): A unit that has won the competition recently feels guilty and allows others to win.

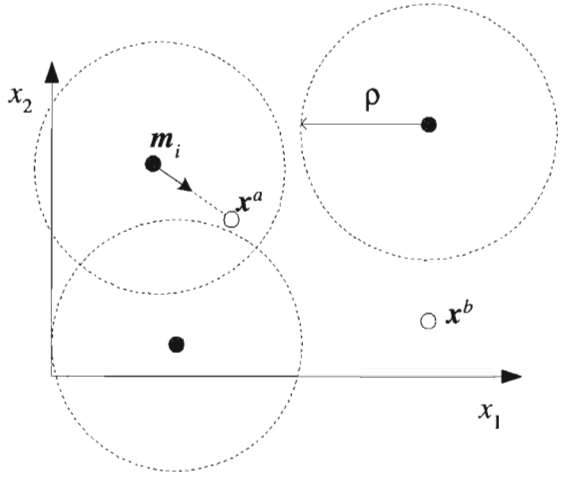

Figure 12.4 The distance from $\boldsymbol{x}^a$ to the closest center is less than the vigilance value ρ and the center is updated as in online k-means. However, $\boldsymbol{x}^b$ is not close enough to any of the centers and a new group should be created at that position.

12.2.2 Adaptive Resonance Theory

The number of groups, k, should be known and specified before the parameters can be calculated. Another approach is *incremental,* where one starts with a single group and adds new groups as they are needed. We discuss the *adaptive resonance theory* (ART) algorithm (Carpenter and Grossberg 1988) as an example of an incremental algorithm. In ART, given an input, all of the output units calculate their values and the one most similar to the input is chosen. This is the unit with the maximum value if the unit uses the dot product as in equation 12.6, or it is the unit with the minimum value if the unit uses the Euclidean distance.

ADAPTIVE RESONANCE THEORY

Let us assume that we use the Euclidean distance. If the minimum value is smaller than a certain threshold value, named the *vigilance,* the update is done as in online k-means. If this distance is larger than vigilance, a new output unit is added and its center is initialized with the instance. This defines a hypersphere whose radius is given by the vigilance defining the volume of scope of each unit; we add a new unit whenever we have an input that is not covered by any unit (see figure 12.4).

VIGILANCE

Denoting vigilance by ρ, we use the following equations at each update:

$$b_i = \|\boldsymbol{m}_i - \boldsymbol{x}^t\| = \min_{l=1}^{k} \|\boldsymbol{m}_l - \boldsymbol{x}^t\| \tag{12.9}$$

$$\begin{cases} \boldsymbol{m}_{k+1} \leftarrow \boldsymbol{x}^t & \text{if } b_i > \rho \\ \Delta \boldsymbol{m}_i = \eta(\boldsymbol{x} - \boldsymbol{m}_i) & \text{otherwise} \end{cases}$$

Putting a threshold on distance is equivalent to putting a threshold on the reconstruction error per instance, and if the distance is Euclidean and the error is defined as in equation 12.4, this indicates that the maximum reconstruction error allowed per instance is the square of vigilance.

12.2.3 Self-Organizing Maps

SELF-ORGANIZING MAP

One way to avoid having dead units is by updating not only the winner but also some of the other units as well. In the *self-organizing map* (SOM) proposed by Kohonen (1990, 1995), unit indices, namely, i as in $\boldsymbol{m}_i$, define a *neighborhood* for the units. When $\boldsymbol{m}_i$ is the closest center, in addition to $\boldsymbol{m}_i$, its neighbors are also updated. For example, if the neighborhood is of size 2, then $\boldsymbol{m}_{i-2}, \boldsymbol{m}_{i-1}, \boldsymbol{m}_{i+1}, \boldsymbol{m}_{i+2}$ are also updated but with less weight as the neighborhood increases. If i is the index of the closest center, the centers are updated as

$$\Delta \boldsymbol{m}_l = \eta\, e(l,i)(\boldsymbol{x}^t - \boldsymbol{m}_l) \tag{12.10}$$

where $e(l,i)$ is the *neighborhood function.* $e(l,i) = 1$ when $l = i$ and decreases as $|l - i|$ increases, for example, as a Gaussian, $\mathcal{N}(i, \sigma)$:

$$e(l,i) = \frac{1}{\sqrt{2\pi}\sigma} \exp\left[-\frac{(l-i)^2}{2\sigma^2}\right] \tag{12.11}$$

For convergence, the support of the neighborhood function decreases in time, for example, σ decreases, and at the end, only the winner is updated.

Because neighboring units are also moved toward the input, we avoid dead units since they get to win competition sometime later, after a little bit of initial help from their neighboring friends (see figure 12.5).

Updating the neighbors has the effect that, even if the centers are randomly initialized, because they are moved toward the same input together, once the system converges, units with neighboring indices will also be neighbors in the input space.

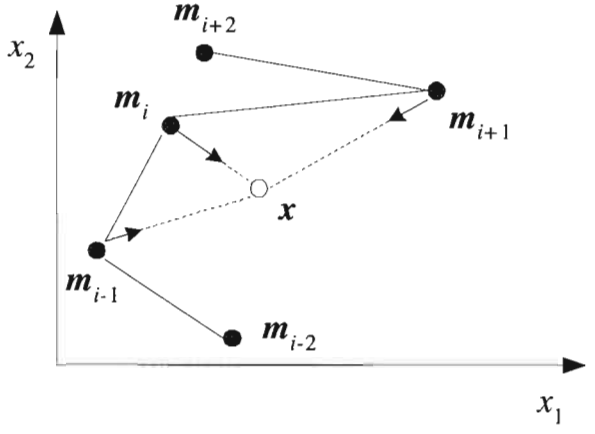

Figure 12.5 In the SOM, not only the closest unit but also its neighbors, in terms of indices, are moved toward the input. Here, neighborhood is 1; $\boldsymbol{m}_i$ and its 1-nearest neighbors are updated. Note here that $\boldsymbol{m}_{i+1}$ is far from $\boldsymbol{m}_i$, but as it is updated with $\boldsymbol{m}_i$, and as $\boldsymbol{m}_i$ will be updated when $\boldsymbol{m}_{i+1}$ is the winner, they will become neighbors in the input space as well.

In most applications, the units are organized as a two-dimensional *map*. That is, each unit will have two indices, $\boldsymbol{m}_{i,j}$, and the neighborhood will be defined in two dimensions. If $\boldsymbol{m}_{i,j}$ is the closest center, the centers are updated as

$$\Delta \boldsymbol{m}_{k,l} = \eta e(k,l,i,j)(\boldsymbol{x}^t - \boldsymbol{m}_{k,l}) \tag{12.12}$$

where the neighborhood function is now in two dimensions. After convergence, this forms a two-dimensional *topographical map* of the original d-dimensional input space. The map contains many units in parts of the space where density is high, and no unit will be dedicated to parts where there is no input. Once the map converges, inputs that are close in the original space are mapped to units that are close in the map. In this regard, the map can be interpreted as doing a nonlinear form of multidimensional scaling, mapping from the original $\boldsymbol{x}$ space to the two dimensions, (i,j). Similarly, if the map is one-dimensional, the units are placed on the curve of maximum density in the input space, as a *principal curve*.

TOPOGRAPHICAL MAP

12.3 Radial Basis Functions

In a multilayer perceptron (chapter 11) where hidden units use the dot product, each hidden unit defines a hyperplane and with the sigmoid nonlinearity, a hidden unit has a value between 0 and 1, coding the position of the instance with respect to the hyperplane. Each hyperplane divides the input space in two, and typically for a given input, many of the hidden units have nonzero output. This is called a *distributed representation* because the input is encoded by the simultaneous activation of many hidden units.

DISTRIBUTED REPRESENTATION

LOCAL REPRESENTATION

Another possibility is to have a *local representation* where for a given input, only one or a few units are active. It is as if these *locally tuned units* partition the input space among themselves and are selective to only certain inputs. The part of the input space where a unit has nonzero response is called its *receptive field.* The input space is then paved with such units.

RECEPTIVE FIELD

Neurons with such response characteristics are found in many parts of the cortex. For example, cells in the visual cortex respond selectively to stimulation that is both local in retinal position and local in angle of visual orientation. Such locally tuned cells are typically arranged in topogrophical cortical maps in which the values of the variables to which the cells respond vary by their position in the map, as in a SOM.

The concept of locality implies a distance function to measure the similarity between the given input $\boldsymbol{x}$ and the position of unit h, $\boldsymbol{m}_h$. Frequently this measure is taken as the Euclidean distance, $\|\boldsymbol{x} - \boldsymbol{m}_h\|$. The response function is chosen to have a maximum where $\boldsymbol{x} = \boldsymbol{m}_h$ and decreasing as they get less similar. Commonly we use the Gaussian function (see figure 12.6):

$$p_h^t = \exp\left[-\frac{\|\boldsymbol{x}^t - \boldsymbol{m}_h\|^2}{2s_h^2}\right] \tag{12.13}$$

Strictly speaking, this is not Gaussian density, but we use the same name anyway. $\boldsymbol{m}_j$ and s_j respectively denote the center and the spread of the local unit j, and as such define a radially symmetric basis function. One can use an elliptic one with different spreads on different dimensions, or even use the full Mahalanobis distance to allow correlated inputs, at the expense of using a more complicated model.

The idea in using such local basis functions is that in the input data, there are groups or clusters of instances and for each such cluster, we

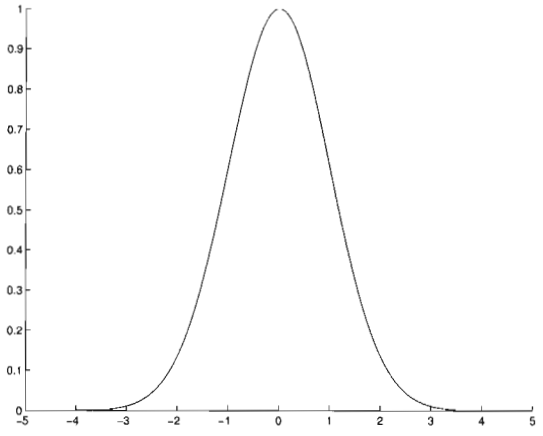

Figure 12.6 The one-dimensional form of the bell-shaped function used in the radial basis function network. This one has $m = 0$ and $s = 1$. It is like a Gaussian but it is not a density; it does not integrate to 1. It is nonzero between $(m - 3s, m + 3s)$, but a more conservative interval is $(m - 2s, m + 2s)$.

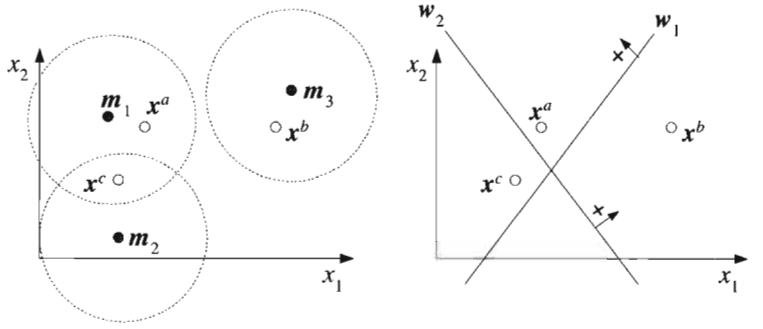
define a basis function, p_h^t, which becomes nonzero if instance $\mathbf{x}^t$ belongs to cluster h. One can use any of the online competitive methods discussed in section 12.2 to find the centers, $\mathbf{m}_h$. There is a simple and effective heuristic to find the spreads: Once we have the centers, for each cluster, we find the most distant instance covered by that cluster and set s_h to half its distance from the center. We could have used one-third, but we prefer to be conservative. We can also use the statistical clustering method, for example, EM on Gaussian mixtures, that we discussed in chapter 7 to find the cluster parameters, namely, means, variances (and covariances).

$p_h^t, h = 1, \ldots, H$ define a new H-dimensional space and form a new representation of $\mathbf{x}^t$. We can also use b_h^t (equation 12.2) to code the input but b_h^t are 0/1; p_h^t have the additional advantage that they code the distance to their center by a value in $(0, 1)$. How fast the value decays to 0 depends on s_h. Figure 12.7 gives an example and compares such a local representation with a distributed representation as used by the multilayer perceptron. Because Gaussians are local, typically we need many more local units than what we would need if we were to use a distributed representation, especially if the input is high-dimensional.

In the case of supervised learning, we can then use this new local rep-



Local representation in the space of (p_1, p_2, p_3)

x^c: (1.0, 1.0, 0.0)

Distributed representation in the space of (h_1, h_2)
x^a: (1.0, 1.0)
x^b: (0.0, 1.0)
x^c: (1.0, 0.0)

Figure 12.7 The difference between local and distributed representations. The values are hard, 0/1, values. One can use soft values in (0, 1) and get a more informative encoding. In the local representation, this is done by the Gaussian RBF that uses the distance to the center, $\boldsymbol{m}_i$, and in the distributed representation, this is done by the sigmoid that uses the distance to the hyperplane, $\boldsymbol{w}_i$.

resentation as the input. If we use a perceptron, we have

$$y^t = \sum_{h=1}^{H} w_h p_h^t + w_0 \tag{12.14}$$

RADIAL BASIS FUNCTION

where H is the number of basis functions. This structure is called a *radial basis function* (RBF) network (Broomhead and Lowe 1988; Moody and Darken 1989). Normally, people do not use RBF networks with more than one layer of Gaussian units. H is the complexity parameter, like the number of hidden units in a multilayer perceptron. Previously we denoted it by k, when it corresponded to the number of centers in the case of unsupervised learning.

Here, we see the advantage of using p_h instead of b_h. Because b_h are 0/1, if equation 12.14 contained b_h instead of the p_h, it would give a piecewise constant approximation with discontuinities at the unit region boundaries. p_h values are soft and lead to a smooth approximation, taking a weighted average while passing from one region to another. We can

easily see that such a network is a universal approximator in that it can approximate any function with desired accuracy, given enough units: We can form a grid in the input space to our desired accuracy, define a unit that will be active for each grid, and set its outgoing weight, w_h, to the desired output value.

This architecture bears much similarity to the nonparametric estimators, for example, Parzen windows, we saw in chapter 8, and p_h may be seen as kernel functions. The difference is that now we do not have a kernel function over all training instances but group them using a clustering method to make do with fewer kernels. H, the number of units, is the complexity parameter, trading off simplicity and accuracy. With more units, we approximate the training data better, but we get a complex model and risk overfitting; too few may underfit. Again, the optimal value is determined by cross-validation.

Once $\mathbf{m}_h$ and s_h are given and fixed, p_h are also fixed. Then w_h can be trained easily batch or online. In the case of regression, this is a linear regression model (with p_h as the inputs) and the w_h can be solved analytically without any iteration (section 4.6). In the case of classification, we need to resort to an iterative procedure. We discussed learning methods for this in chapter 10 and do not repeat them here.

What we do here is a two-stage process: We use an unsupervised method for determining the centers, then build a supervised layer on top of that. This is called *hybrid learning.* We can also learn all parameters, including $\mathbf{m}_h$ and s_h, in a supervised manner. The radial basis function of equation 12.13 is differentiable and we can backpropagate, just as we backpropagated in a multilayer perceptron to update the first-layer weights. The structure is similar to a multilayer perceptron with p_h as the hidden units, $\mathbf{m}_h$ and s_h as the first-layer parameters, the Gaussian as the activation function in the hidden layer, and w_h as the second-layer weights (see figure 12.8).

HYBRID LEARNING

But before we discuss this, we should remember that training a two-layer network is slow. Hybrid learning trains one layer at a time and is faster. Another technique, called the *anchor* method, sets the centers to the randomly chosen patterns from the training set without any further update. It is adequate if there are many units.

ANCHOR

On the other hand, the accuracy normally is not as high as when a completely supervised method is used. Consider the case when the input is uniformly distributed. Then k-means clustering places the units uniformly. If the function is changing significantly in a small part of the

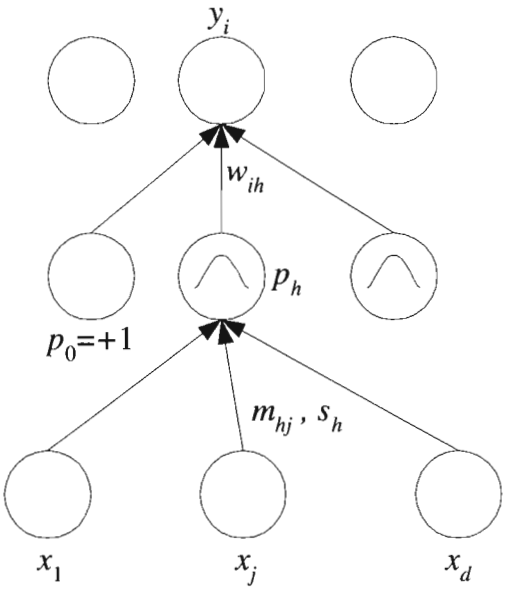

Figure 12.8 The RBF network where p_h are the hidden units using the bell-shaped activation function. $\boldsymbol{m}_h, s_h$ are the first-layer parameters, and $\boldsymbol{w}_i$ are the second-layer weights.

space, it is a better idea to have as many centers in places where the the function changes fast, to make the error as small as possible; this is what the completely supervised method would do.

Let us discuss how all of the parameters can be trained in a fully supervised manner. The approach is the same as backpropagation applied to multilayer perceptrons. Let us see the case of regression with multiple outputs. The batch error is

$$E(\{\boldsymbol{m}_h, s_h, w_{ih}\}_{i,h}|\mathcal{X}) = \frac{1}{2}\sum_t \sum_i (r_i^t - y_i^t)^2 \tag{12.15}$$

where

$$y_i^t = \sum_{h=1}^{H} w_{ih} p_h^t + w_{i0} \tag{12.16}$$

Using gradient descent, we get the following update rule for the second-

layer weights:

$$\Delta w_{ih} = \eta \sum_t (r_i^t - y_i^t) p_h^t \tag{12.17}$$

This is the usual perceptron update rule, with p_h as the inputs. Typically, p_h do not overlap much and at each iteration, only a few p_h are nonzero and only their w_h are updated. That is why RBF networks learn very fast, and faster than multilayer perceptrons that use a distributed representation.

Similarly, we can get the update equations for the centers and spreads by backpropagation (chain rule):

$$\Delta m_{hj} = \eta \sum_t \left[\sum_i (r_i^t - y_i^t) w_{ih} \right] p_h^t \frac{(x_j^t - m_{hj})}{s_h^2} \tag{12.18}$$

$$\Delta s_h = \eta \sum_t \left[\sum_i (r_i^t - y_i^t) w_{ih} \right] p_h^t \frac{\|\mathbf{x}^t - \mathbf{m}_h\|^2}{s_h^3} \tag{12.19}$$

Let us compare equation 12.18 with equation 12.5: First, here we use p_h instead of b_h, which means that not only the closest one but all units are updated, depending on their centers and spreads. Second, here the update is supervised and contains the backpropagated error term. The update depends not only on the input but also on the final error $(r_i^t - y_i^t)$, the effect of the unit on the output, w_{ih}, the activation of the unit, p_h, and the input, $(\mathbf{x} - \mathbf{m}_i)$.

In the case of classification, we have

$$y_i^t = \frac{\exp\left[\sum_h w_{ih} p_h^t + w_{i0}\right]}{\sum_k \exp\left[\sum_h w_{kh} p_h^t + w_{k0}\right]} \tag{12.20}$$

and the cross-entropy error is

$$E(\{\mathbf{m}_h, s_h, w_{ih}\}_{i,h} | \mathcal{X}) = -\sum_t \sum_i r_i^t \log y_i^t \tag{12.21}$$

Update rules can similarly be derived using gradient descent (exercise 2).

Let us look again at equation 12.14: For any input, if p_h is nonzero, then it contributes w_h to the output. Its contribution is a constant fit, as given by w_h. Normally Gaussians do not overlap much, and one or two of them have a nonzero p_h value. In any case, only few units contribute to the output. w_0 is the constant offset and is added to the weighted sum

of the active (nonzero) units. We also see that $y = w_0$ if all p_h are 0. We can therefore view w_0 as the "default" value of y: If no Gaussian is active, then the output is given by this value. So a possibility is to make this "default model" more powerful. For example, we can write

$$y^t = \sum_{h=1}^{H} w_h p_h^t + \mathbf{v}^T \mathbf{x}^t + v_0 \tag{12.22}$$

In this case, the default model is linear: $\mathbf{v}^T \mathbf{x}^t + v_0$. When they are nonzero, Gaussians work as "exceptions" and modify the output to make up for the difference between the desired output and the output of the default model. Such a model can be trained in a supervised manner, and the default model can be trained together with the w_h (exercise 3).

12.4 Incorporating Rule-Based Knowledge

PRIOR KNOWLEDGE

The training of any learning system can be much simpler if we manage to incorporate *prior knowledge* to initialize the system. For example, prior knowledge may be available in the form of a set of rules that specify the input/output mapping that the model, for example, the RBF network, has to learn. This occurs frequently in industrial and medical applications where rules can be given by experts. Similarly, once a network has been trained, rules can be extracted from the solution in such a way as to better understand the solution to the problem.

The inclusion of prior knowledge has the additional advantage that if the network is required to extrapolate into regions of the input space where it has not seen any training data, it can rely on this prior knowledge. Furthermore, in many control applications, the network is required to make reasonable predictions right from the beginning. Before it has seen sufficient training data, it has to rely primarily on this prior knowledge.

In many applications we are typically told some basic rules that we try to follow in the beginning but that are then refined and altered through experience. The better our initial knowledge of a problem, the faster we can achieve good performance and the less training that is required.

Such inclusion of prior knowledge or extraction of learned knowledge is easy to do with RBF networks because the units are local. This makes *rule extraction* easier (Tresp, Hollatz, and Ahmad 1997). An example is

RULE EXTRACTION

$$\text{IF } ((x_1 \approx a) \text{ AND } (x_2 \approx b)) \text{ OR } (x_3 \approx c) \text{ THEN } y = 0.1 \tag{12.23}$$

where $x_1 \approx a$ means "x_1 is approximately a." In the RBF framework, this rule is encoded by two Gaussian units as

$$p_1 = \exp\left[-\frac{(x_1 - a)^2}{2s_1^2}\right] \cdot \exp\left[-\frac{(x_2 - b)^2}{2s_2^2}\right] \text{ with } w_1 = 0.1$$

$$p_2 = \exp\left[-\frac{(x_3 - c)^2}{2s_3^2}\right] \text{ with } w_2 = 0.1$$

"Approximately equal to" is modeled by a Gaussian where the center is the ideal value and the spread denotes the allowed difference around this ideal value. Conjunction is the product of two univariate Gaussians that is a bivariate Gaussian. Then, the first product term can be handled by a two-dimensional, namely, $\boldsymbol{x} = [x_1, x_2]$, Gaussian centered at (a, b), and the spreads on the two dimensions are given by s_1 and s_2. Disjunction is modeled by two separate Gaussians, each one handling one of the disjuncts.

Given labeled training data, the parameters of the RBF network so constructed can be fine-tuned after the initial construction, using a small value of η.

FUZZY RULE
FUZZY MEMBERSHIP FUNCTION

This formulation is related to the fuzzy logic approach where equation 12.23 is named a *fuzzy rule.* The Gaussian basis function that checks for approximate equality corresponds to a *fuzzy membership function* (Berthold 1999; Cherkassky and Mulier 1998).

12.5 Normalized Basis Functions

In equation 12.14, for an input, it is possible that all of the p_h are 0. In some applications, we may want to have a *normalization* step to make sure that the values of the local units sum up to 1, thus making sure that for any input there is at least one nonzero unit:

$$g_h^t = \frac{p_h^t}{\sum_{l=1}^{H} p_l^t} = \frac{\exp[-\|\boldsymbol{x}^t - \boldsymbol{m}_h\|^2 / 2s_h^2]}{\sum_l \exp[-\|\boldsymbol{x}^t - \boldsymbol{m}_l\|^2 / 2s_l^2]} \tag{12.24}$$

An example is given in figure 12.9. Taking p_h as $p(\boldsymbol{x}|h)$, g_h correspond to $p(h|\boldsymbol{x})$, the posterior probability that $\boldsymbol{x}$ belongs to unit h. It is as if the units divide the input space among themselves. We can think of g_h as a classifier in itself, choosing the responsible unit for a given input. This classification is done based on distance, as in a parametric Gaussian classifier (chapter 5).

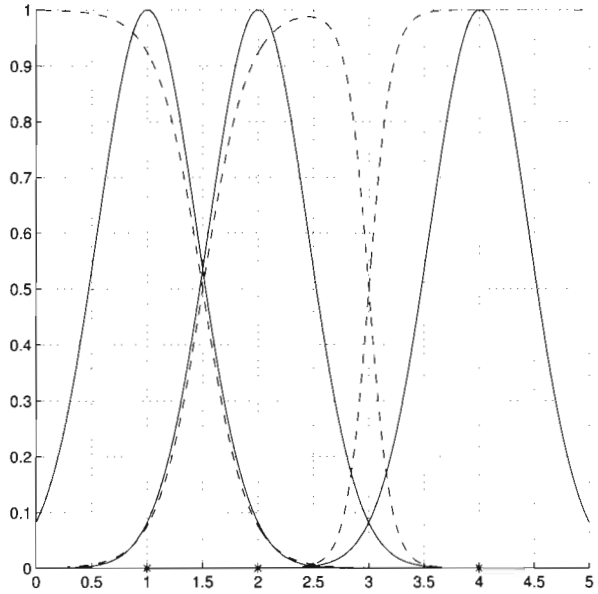

Figure 12.9 (-) Before and (- -) after normalization for three Gaussians whose centers are denoted by '*'. Note how the nonzero region of a unit depends also on the positions of other units. If the spreads are small, normalization implements a harder split; with large spreads, units overlap more.

The output is a weighted sum

$$y_i^t = \sum_{h=1}^{H} w_{ih} g_h^t \tag{12.25}$$

where there is no need for a bias term because there is at least one nonzero g_h for each $\boldsymbol{x}$. Using g_h instead of p_h does not introduce any extra parameters; it only couples the units together: p_h depends only on $\boldsymbol{m}_h$ and s_h, but g_h, because of normalization, depends on the centers and spreads of all of the units.

In the case of regression, we have the following update rules using gradient descent:

$$\Delta w_{ih} = \eta \sum_t (r_i^t - y_i^t) g_h^t \tag{12.26}$$

$$\Delta m_{hj} = \eta \sum_t \sum_i (r_i^t - y_i^t)(w_{ih} - y_i^t) g_h^t \frac{(x_j^t - m_{hj})}{s_h^2} \tag{12.27}$$

The update rule for s_h as well as the rules for classification can similarly be derived. Let us compare these with the update rules for the RBF with unnormalized Gaussians (equation 12.17). Here, we use g_h instead of p_h, which makes a unit's update dependent not only on its own parameters, but also on the centers and spreads of other units as well. Comparing equation 12.27 with equation 12.18, we see that instead of w_{ih}, we have $(w_{ih} - y_i^t)$, which shows the role of normalization on the output. The "responsible" unit wants to decrease the difference between its output, w_{ih}, and the final output, y_i^t, proportional to its responsibility, g_h.

12.6 Competitive Basis Functions

As we have seen up until now, in an RBF network the final output is determined as a weighted sum of the contributions of the local units. Though the units are local, it is the final weighted sum that is important and that we want to make as close as possible to the required output. For example, in regression we minimize equation 12.15, which is based on the probabilistic model

$$p(\mathbf{r}^t|\mathbf{x}^t) = \prod_i \frac{1}{\sqrt{2\pi}\sigma} \exp\left[-\frac{(r_i^t - y_i^t)^2}{2\sigma^2}\right] \tag{12.28}$$

where y_i^t is given by equation 12.16 (unnormalized) or equation 12.25 (normalized). In either case, we can view the model as a *cooperative* one since the units cooperate to generate the final output, y_i^t. We now discuss the approach using *competitive basis functions* where we assume that the output is drawn from a mixture model

COMPETITIVE BASIS FUNCTIONS

$$p(\mathbf{r}^t|\mathbf{x}^t) = \sum_{h=1}^{H} p(h|\mathbf{x}^t) p(\mathbf{r}^t|h, \mathbf{x}^t) \tag{12.29}$$

$p(h|\mathbf{x}^t)$ are the mixture proportions and $p(\mathbf{r}^t|h, \mathbf{x}^t)$ are the mixture components generating the output if that component is chosen. Note that both of these terms depend on the input $\mathbf{x}$.

The mixture proportions are

$$p(h|\mathbf{x}) = \frac{p(\mathbf{x}|h)p(h)}{\sum_l p(\mathbf{x}|l)p(l)} \tag{12.30}$$

$$g_h^t = \frac{a_h \exp[-\|\boldsymbol{x}^t - \boldsymbol{m}_h\|^2/2s_h^2]}{\sum_l a_l \exp[-\|\boldsymbol{x}^t - \boldsymbol{m}_l\|^2/2s_l^2]} \tag{12.31}$$

We generally assume a_h to be equal and ignore them. Let us first take the case of regression where the components are Gaussian. In equation 12.28, noise is added to the weighted sum; here, one component is chosen and noise is added to its output, y_{ih}^t.

Using the mixture model of equation 12.29, the log likelihood is

$$\mathcal{L}(\{\boldsymbol{m}_h, s_h, w_{ih}\}_{i,h}|\mathcal{X}) = \sum_t \log \sum_h g_h^t \exp\left[-\frac{1}{2}\sum_i (r_i^t - y_{ih}^t)^2\right] \tag{12.32}$$

where $y_{ih}^t = w_{ih}$ is the constant fit done by component h for output i, which, strictly speaking, does not depend on $\boldsymbol{x}$. (In section 12.8.2, we discuss the case of competitive mixture of experts where the local fit is a linear function of $\boldsymbol{x}$.) We see that if g_h^t is 1, then it is responsible for generating the right output and needs to minimize the squared error of its prediction, $\sum_i (r_i^t - y_{ih}^t)^2$.

Using gradient ascent to maximize the log likelihood, we get

$$\Delta w_{ih} = \eta \sum_t (r_i^t - y_{ih}^t) f_h^t \tag{12.33}$$

where

$$f_h^t = \frac{g_h^t \exp[-\frac{1}{2}\sum_i (r_i^t - y_{ih}^t)^2]}{\sum_l g_l^t \exp[-\frac{1}{2}\sum_i (r_i^t - y_{il}^t)^2]} \tag{12.34}$$

$$p(h|\boldsymbol{r}, \boldsymbol{x}) = \frac{p(h|\boldsymbol{x})p(\boldsymbol{r}|h, \boldsymbol{x})}{\sum_l p(l|\boldsymbol{x})p(\boldsymbol{r}|l, \boldsymbol{x})} \tag{12.35}$$

$g_h^t \equiv p(h|\boldsymbol{x}^t)$ is the posterior probability of unit h given the input, and it depends on the centers and spreads of all of the units. $f_h^t \equiv p(h|\boldsymbol{r}, \boldsymbol{x}^t)$ is the posterior probability of unit h given the input and the desired output, also taking the error into account in choosing the responsible unit.

Similarly, we can derive a rule to update the centers:

$$\Delta m_{hj} = \eta \sum_t (f_h^t - g_h^t) \frac{(x_j^t - m_{hj})}{s_h^2} \tag{12.36}$$

f_h is the posterior probability of unit h also taking the required output into account, whereas g_h is the posterior probability using only the input space information. Their difference is the error term for the centers. Δs_h can be similarly derived. In the cooperative case, there is no force on the

units to be localized. To decrease the error, means and spreads can take any value; it is even possible sometimes for the spreads to increase and flatten out. In the competitive case, however, to increase the likelihood, units are forced to be localized with more separation between them and smaller spreads.

In classification, each component by itself is a multinomial. Then the log likelihood is

$$\mathcal{L}(\{\boldsymbol{m}_h, s_h, w_{ih}\}_{i,h}|\mathcal{X}) = \sum_t \log \sum_h g_h^t \prod_i (y_{ih}^t)^{r_i^t} \tag{12.37}$$

$$= \sum_t \log \sum_h g_h^t \exp\left[\sum_i r_i^t \log y_{ih}^t\right] \tag{12.38}$$

where

$$y_{ih}^t = \frac{\exp w_{ih}}{\sum_k \exp w_{kh}} \tag{12.39}$$

Update rules for w_{ih}, $\boldsymbol{m}_h$, and s_h can be derived using gradient ascent, which will include

$$f_h^t = \frac{g_h^t \exp[\sum_i r_i^t \log y_{ih}^t]}{\sum_l g_l^t \exp[\sum_i r_i^t \log y_{il}^t]} \tag{12.40}$$

In chapter 7, we discussed the EM algorithm for fitting Gaussian mixtures to data. It is possible to generalize EM for supervised learning as well. Actually, calculating f_h^t corresponds to the E-step. $f_h^t \equiv p(\boldsymbol{r}|h, \boldsymbol{x}^t)$ replaces $p(h|\boldsymbol{x}^t)$, which we used in the E-step in chapter 7 when the application was unsupervised. In the M-step for regression, we update the parameters as

$$\boldsymbol{m}_h = \frac{\sum_t f_h^t \boldsymbol{x}^t}{\sum_t f_h^t} \tag{12.41}$$

$$\mathbf{S}_h = \frac{\sum_t f_h^t (\boldsymbol{x}^t - \boldsymbol{m}_h)(\boldsymbol{x}^t - \boldsymbol{m}_h)^T}{\sum_t f_h^t} \tag{12.42}$$

$$w_{ih} = \frac{\sum_t f_h^t r_i^t}{\sum_t f_h^t} \tag{12.43}$$

We see that w_{ih} is a weighted average where weights are the posterior probabilities of units, given the input and the desired output. In the case of classification, the M-step has no analytical solution and one needs to resort to an iterative procedure, for example, gradient ascent (Jordan and Jacobs 1994).

12.7 Learning Vector Quantization

Let us say we have H units for each class, already labeled by those classes. These units are initialized with random instances from their classes. At each iteration, we find the unit, $\boldsymbol{m}_i$, that is closest to the input instance in Euclidean distance and use the following update rule:

$$\begin{cases} \Delta \boldsymbol{m}_i = \eta(\boldsymbol{x}^t - \boldsymbol{m}_i) & \text{if } \boldsymbol{x}^t \text{ and } \boldsymbol{m}_i \text{ have the same class label} \\ \Delta \boldsymbol{m}_i = -\eta(\boldsymbol{x}^t - \boldsymbol{m}_i) & \text{otherwise} \end{cases} \tag{12.44}$$

If the closest center has the correct label, it is moved toward the input to better represent it. If it belongs to the wrong class, it is moved away from the input in the expectation that if it is moved sufficiently away, a center of the correct class will be the closest in a future iteration. This is the *learning vector quantization* (LVQ) model proposed by Kohonen (1990, 1995).

LEARNING VECTOR QUANTIZATION

The LVQ update equation is analogous to equation 12.36 where the direction in which the center is moved depends on the difference between two values: our prediction of the winner unit based on the input distances and what the winner should be based on the required output.

12.8 Mixture of Experts

In RBFs, corresponding to each local patch we give a constant fit. In the case where for any input, we have one g_h 1 and all others 0, we get a piecewise constant approximation where for output i, the local fit by patch h is given by w_{ih}. From the Taylor expansion, we know that at each point, the function can be written as

$$f(x) = f(a) + (x - a)f'(a) + \cdots \tag{12.45}$$

Thus a constant approximation is good if x is close enough to a and $f'(a)$ is close to 0—that is, if $f(x)$ is flat around a. If this is not the case, we need to divide the space into a large number of patches, which is particularly serious when the input dimensionality is high, due to the curse of dimensionality.

PIECEWISE LINEAR APPROXIMATION

MIXTURE OF EXPERTS

An alternative is to have a *piecewise linear approximation* by taking into account the next term in the Taylor expansion, namely, the linear term. This is what is done by *mixture of experts* (Jacobs et al. 1991). We write

$$y_i^t = \sum_{h=1}^{H} w_{ih} g_h^t \tag{12.46}$$

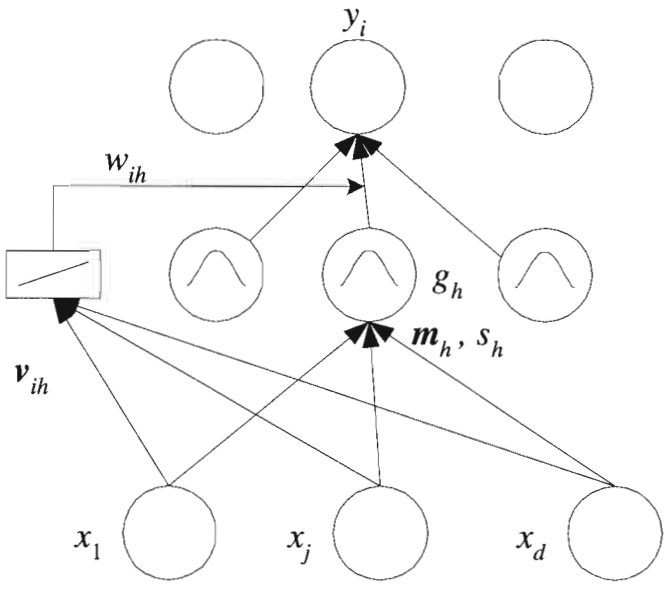

Figure 12.10 The mixture of experts can be seen as an RBF network where the second-layer weights are outputs of linear models. Only one linear model is shown for clarity.

which is the same as equation 12.25 but here, w_{ih}, the contribution of patch h to output i is not a constant but a linear function of the input:

$$w_{ih}^t = \mathbf{v}_{ih}^T \mathbf{x}^t \tag{12.47}$$

$\mathbf{v}_{ih}$ is the parameter vector that defines the linear function and includes a bias term, making the mixture of experts a generalization of the RBF network. The unit activations can be taken as normalized RBFs:

$$g_h^t = \frac{\exp[-\|\mathbf{x}^t - \mathbf{m}_h\|^2/2s_h^2]}{\sum_l \exp[-\|\mathbf{x}^t - \mathbf{m}_l\|^2/2s_l^2]} \tag{12.48}$$

This can be seen as an RBF network except that the second-layer weights are not constants but are outputs of linear models (see figure 12.10). Jacobs et al. (1991) view this in another way: They consider $\mathbf{w}_h$ as linear models, each taking the input, and call them *experts*. g_h are considered to be the outputs of a *gating network*. The gating network works as a classifier does with its outputs summing to 1, assigning the input to one of the experts (see figure 12.11).

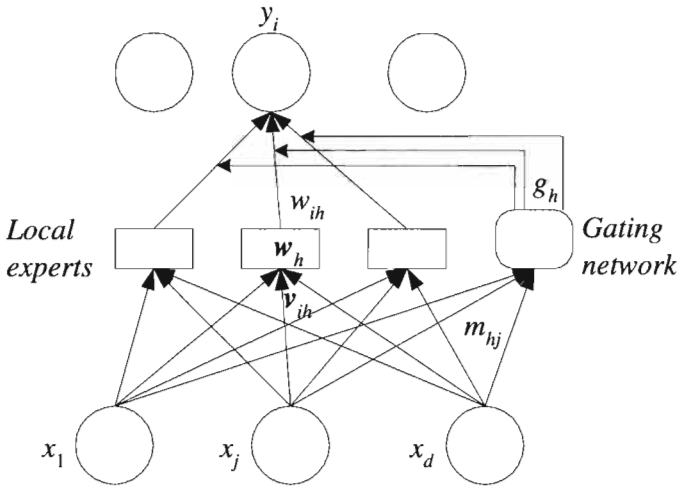

Figure 12.11 The mixture of experts can be seen as a model for combining multiple models. $\boldsymbol{w}_h$ are the models and the gating network is another model determining the weight of each model, as given by g_h. Viewed in this way, neither the experts nor the gating are restricted to be linear.

Considering the gating network in this manner, any classifier can be used in gating. When $\boldsymbol{x}$ is high-dimensional, using local Gaussian units may require a large number of experts and Jacobs et al. (1991) propose to take

$$g_h^t = \frac{\exp[\boldsymbol{m}_h^T \boldsymbol{x}^t]}{\sum_l \exp[\boldsymbol{m}_l^T \boldsymbol{x}^t]} \tag{12.49}$$

which is a linear classifier. Note that $\boldsymbol{m}_h$ are no longer centers but hyperplanes, and as such include bias values. This gating network is implementing a classification where it is dividing linearly the input region for which expert h is responsible from the expertise regions of other experts. As we will see again in chapter 15, the mixture of experts is a general architecture for combining multiple models; the experts and the gating may be nonlinear, for example, contain multilayer perceptrons, instead of linear perceptrons (exercise 5).

An architecture similar to the mixture of experts and running line smoother (section 8.6.3) has been proposed by Bottou and Vapnik (1992). In their approach, no training is done initially. When a test instance is

given, a subset of the data close to the test instance is chosen from the training set (as in the k-nearest neighbor, but with a large k), a simple model, for example, a linear classifier, is trained with this local data, the prediction is made for the instance, and then the model is discarded. For the next instance, a new model is created, and so on. On a handwritten digit recognition application, this model has less error than the multilayer perceptron, k-nearest neighbor, and Parzen windows; the disadvantage is the need to train a new model on the fly for each test instance.

12.8.1 Cooperative Experts

In the cooperative case, y_i^t is given by equation 12.46, and we would like to make it as close as possible to the required output, r_i^t. In regression, the error function is

$$E(\{\boldsymbol{m}_h, s_h, w_{ih}\}_{i,h}|\mathcal{X}) = \frac{1}{2}\sum_t \sum_i (r_i^t - y_i^t)^2 \tag{12.50}$$

Using gradient descent, second-layer (expert) weight parameters are updated as

$$\Delta \boldsymbol{v}_{ih} = \eta \sum_t (r_i^t - y_i^t) g_h^t \boldsymbol{x}^t \tag{12.51}$$

Compared with equation 12.26, we see that the only difference is that this new update is a function of the input.

If we use softmax gating (equation 12.49), using gradient descent we have the following update rule for the hyperplanes:

$$\Delta m_{hj} = \eta \sum_t \sum_i (r_i^t - y_i^t)(w_{ih}^t - y_i^t) g_h^t x_j^t \tag{12.52}$$

If we use radial gating (equation 12.48), only the last term, $\partial p_h / \partial m_{hj}$, differs.

In classification, we have

$$y_i = \frac{\exp\left[\sum_h w_{ih} g_h^t\right]}{\sum_k \exp\left[\sum_h w_{kh} g_h^t\right]} \tag{12.53}$$

with $w_{ih} = \boldsymbol{v}_{ih}^T \boldsymbol{x}$, and update rules can be derived to minimize the cross-entropy using gradient descent (exercise 6).

12.8.2 Competitive Experts

Just like the competitive RBFs, we have

$$\mathcal{L}(\{\boldsymbol{m}_h, s_h, w_{ih}\}_{i,h}|\mathcal{X}) = \sum_t \log \sum_h g_h^t \exp\left[-\frac{1}{2}\sum_i (r_i^t - y_{ih}^t)^2\right] \tag{12.54}$$

where $y_{ih}^t = w_{ih}^t = \boldsymbol{v}_{ih}\boldsymbol{x}^t$. Using gradient ascent, we get

$$\Delta \boldsymbol{v}_{ih} = \eta \sum_t (r_i^t - y_{ih}^t) f_h^t \boldsymbol{x}^t \tag{12.55}$$

$$\Delta \boldsymbol{m}_h = \eta \sum_t (f_h^t - g_h^t) \boldsymbol{x}^t \tag{12.56}$$

assuming softmax gating as given in equation 12.49.

In classification, we have

$$\mathcal{L}(\{\boldsymbol{m}_h, s_h, w_{ih}\}_{i,h}|\mathcal{X}) = \sum_t \log \sum_h g_h^t \prod_i (y_{ih}^t)^{r_i^t} \tag{12.57}$$

$$= \sum_t \log \sum_h g_h^t \exp\left[\sum_i r_i^t \log y_{ih}^t\right] \tag{12.58}$$

where

$$y_{ih}^t = \frac{\exp w_{ih}^t}{\sum_k \exp w_{kh}^t} = \frac{\exp[\boldsymbol{v}_{ih}\boldsymbol{x}^t]}{\sum_k \exp[\boldsymbol{v}_{kh}\boldsymbol{x}^t]} \tag{12.59}$$

Jordan and Jacobs (1994) generalize EM for the competitive case with local linear models. Alpaydın and Jordan (1996) compare cooperative and competitive models for classification tasks and see that the cooperative model is generally more accurate but the competitive version learns faster. This is because in the cooperative case, models overlap more and implement a smoother approximation, and thus it is preferable in regression problems. The competitive model makes a harder split; generally only one expert is active for an input and therefore learning is faster.

12.9 Hierarchical Mixture of Experts

HIERARCHICAL MIXTURE OF EXPERTS

In figure 12.11, we see a set of experts and a gating network that chooses one of the experts as a function of the input. In a *hierarchical mixture of experts*, we replace each expert with a complete system of mixture of experts in a recursive manner (Jordan and Jacobs 1994). This architecture

may be seen as a decision tree (chapter 9) where gating networks can be seen as decision nodes. When the gating network is linear, this is like the linear multivariate decision tree discussed in section 9.6. The difference is that the gating network does not make a hard decision but takes a weighted sum of contributions coming from the children. Leaf nodes are linear models, and their predictions are averaged and propagated up the tree. The root gives the final output, which is a weighted average of all of the leaves. This is a *soft decision tree* as opposed to the decision trees we saw before where only one path from the root to a leaf is taken.

Once an architecture is chosen—namely, the depth, the experts, and the gating models—the whole tree can be learned from a labeled sample. Jordan and Jacobs (1994) derive both gradient descent and EM learning rules for such an architecture.

12.10 Notes

An RBF network can be seen as a neural network, implemented by a network of simple processing units. It differs from a multilayer perceptron in that the first and second layers implement different functions. Omohundro (1987) discusses how local models can be implemented as neural networks and also addresses hierarchical data structures for fast localization of relevant local units. Specht (1991) shows how Parzen windows can be implemented as a neural network.

Platt (1991) proposed an incremental version of RBF where new units are added as necessary. Fritzke (1995) similarly proposed a growing version of SOM.

Lee (1991) compares k-nearest neighbor, multilayer perceptron, and RBF network on a handwritten digit recognition application and concludes that these three methods all have small error rates. RBF networks learn faster than backpropagation on a multilayer perceptron but use more parameters. Both of these methods are superior to the k-NN in terms of classification speed and memory need. Such practical constraints like time, memory, and computational complexity may be more important than small differences in error rate in real-world applications.

Kohonen's SOM (1990, 1995) is one of the most popular neural network methods, having been used in a variety of applications including exploratory data analysis and as a preprocessing stage before a super-

vised learner. One interesting and successful application is the traveling salesman problem (Angeniol, Vaubois, and Le Texier 1988).

12.11 Exercises

1. Show an RBF network that implements XOR.
2. Derive the update equations for the RBF network for classification (equations 12.20 and 12.21).
3. Show how the system given in equation 12.22 can be trained.
4. Compare the number of parameters of a mixture of experts architecture with an RBF network.
5. Formalize a mixture of experts architecture where the experts and the gating network are multilayer perceptrons. Derive the update equations for regression and classification.
6. Derive the update equations for the cooperative mixture of experts for classification.
7. Derive the update equations for the competitive mixture of experts for classification.
8. Formalize the hierarchical mixture of experts architecture with two levels. Derive the update equations using gradient descent for regression and classification.

13 *Hidden Markov Models*

We relax the assumption that instances in a sample are independent and introduce Markov models to model input sequences as generated by a parametric random process. We discuss how this modeling is done as well as an algorithm for learning the parameters of such a model from example sequences.

13.1 Introduction

UNTIL NOW, we assumed that the instances that constitute a sample are iid. This has the advantage that the likelihood of the sample is simply the product of the likelihoods of the individual instances. This assumption, however, is not valid in applications where successive instances are dependent. For example, in a word successive letters are dependent; in English 'h' is very likely to follow 't' but not 'x'. Such processes where there is a *sequence* of observations—for example, letters in a word, base pairs in a DNA sequence—cannot be modeled as simple probability distributions. A similar example is speech recognition where speech utterances are composed of speech primitives called phonemes; only certain sequences of phonemes are allowed, which are the words of the language. At a higher level, words can be written or spoken in certain sequences to form a sentence as defined by the syntactic and semantic rules of the language.

A sequence can be characterized as being generated by a *parametric random process.* In this chapter, we discuss how this modeling is done and also how the parameters of such a model can be learned from a training sample of example sequences.

13.2 Discrete Markov Processes

Consider a system that at any time is in one of a set of N distinct states: $S_1, S_2, \ldots, S_N$. The state at time t is denoted as $q_t, t = 1, 2, \ldots$, so for example $q_t = S_i$ means that at time t, the system is in state S_i. Though we write "time" as if this should be a temporal sequence, the methodology is valid for any sequencing, be it in time, space, position on the DNA string, and so forth.

At regularly spaced discrete times, the system moves to a state with a given probability, depending on the values of the previous states:

$$P(q_{t+1} = S_j | q_t = S_i, q_{t-1} = S_k, \cdots)$$

MARKOV MODEL

For the special case of a first-order *Markov model*, the state at time $t+1$ depends only on state at time t, regardless of the states in the previous times:

$$P(q_{t+1} = S_j | q_t = S_i, q_{t-1} = S_k, \cdots) = P(q_{t+1} = S_j | q_t = S_i) \tag{13.1}$$

This corresponds to saying that, given the present state, the future is independent of the past. This is just a mathematical version of the saying, Today is the first day of the rest of your life.

We further simplify the model—that is, regularize—by assuming that these *transition probabilities* are independent of time:

TRANSITION PROBABILITIES

$$a_{ij} \equiv P(q_{t+1} = S_j | q_t = S_i) \tag{13.2}$$

satisfying

$$a_{ij} \geq 0 \text{ and } \sum_{j=1}^{N} a_{ij} = 1 \tag{13.3}$$

So, going from S_i to S_j has the same probability no matter when it happens, or where it happens in the observation sequence. $\mathbf{A} = [a_{ij}]$ is a $N \times N$ matrix whose rows sum to 1.

STOCHASTIC AUTOMATON

This can be seen as a *stochastic automaton* (see figure 13.1). From each state S_i, the system moves to state S_j with probability a_{ij}, and this probability is the same for any t. The only special case is the first state.

INITIAL PROBABILITIES

We define *initial probabilities*, π_i, which is the probability that the first state in the sequence is S_i:

$$\pi_i \equiv P(q_1 = S_i) \tag{13.4}$$

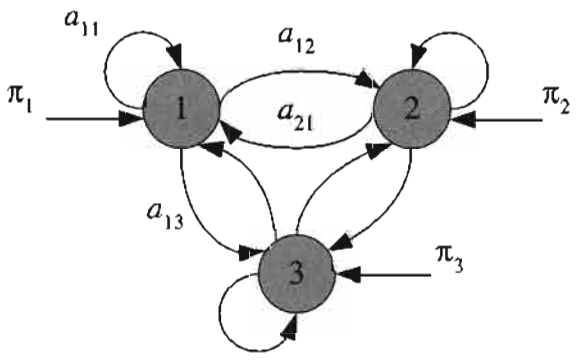

Figure 13.1 Example of a Markov model with three states is a stochastic automaton. π_i is the probability that the system starts in state S_i, and a_{ij} is the probability that the system moves from state S_i to state S_j.

satisfying

$$\sum_{i=1}^{N} \pi_i = 1 \tag{13.5}$$

$\mathbf{\Pi} = [\pi_i]$ is a vector of N elements that sum to 1.

OBSERVABLE MARKOV MODEL

In an *observable Markov model*, the states are observable. At any time t, we know q_t, and as the system moves from one state to another, we get an observation sequence that is a sequence of states. The output of the process is the set of states at each instant of time where each state corresponds to a physical observable event.

We have an observation sequence O that is the state sequence $O = Q = \{q_1 q_2 \cdots q_T\}$, whose probability is given as

$$P(O = Q|\mathbf{A}, \mathbf{\Pi}) = P(q_1) \prod_{t=2}^{T} P(q_t|q_{t-1}) = \pi_{q_1} a_{q_1 q_2} \cdots a_{q_{T-1} q_T} \tag{13.6}$$

π_{q_1} is the probability that the first state is q_1, $a_{q_1 q_2}$ is the probability of going from q_1 to q_2, and so on. We multiply these probabilities to get the probability of the whole sequence.

Let us now see an example (Rabiner and Juang 1986) to help us demonstrate: Assume we have N urns where each urn contains balls of only one color. So there is an urn of red balls, another of blue balls, and so forth.

Somebody draws balls from urns one by one and shows us their color. Let q_t denote the color of the ball drawn at time t. Let us say we have three states:

S_1 : red, S_2 = blue, S_3 : green

with initial probabilities:

$\mathbf{\Pi} = [0.5, 0.2, 0.3]^T$

a_{ij} is the probability of drawing from urn j (a ball of color j) after drawing a ball of color i from urn i. The transition matrix is, for example,

$$\mathbf{A} = \begin{bmatrix} 0.4 & 0.3 & 0.3 \\ 0.2 & 0.6 & 0.2 \\ 0.1 & 0.1 & 0.8 \end{bmatrix}$$

Given $\mathbf{\Pi}$ and $\mathbf{A}$, it is easy to generate K random sequences each of length T. Let us see how we can calculate the probability of a sequence: Assume that the first four balls are "red, red, green, green." This corresponds to the observation sequence $O = \{S_1, S_1, S_3, S_3\}$. Its probability is

$$\begin{aligned} P(O|\mathbf{A}, \mathbf{\Pi}) &= P(S_1) \cdot P(S_1|S_1) \cdot P(S_3|S_1) \cdot P(S_3|S_3) \\ &= \pi_1 \cdot a_{11} \cdot a_{13} \cdot a_{33} \\ &= 0.5 \cdot 0.4 \cdot 0.3 \cdot 0.8 = 0.048 \end{aligned} \tag{13.7}$$

Now, let us see how we can learn the parameters, $\mathbf{\Pi}, \mathbf{A}$: Given K sequences of length T, where q_t^k is the state at time t of sequence k, the initial probability estimate is the number of sequences starting with S_i divided by the number of sequences:

$$\hat{\pi}_i = \frac{\#\{\text{sequences starting with } S_i\}}{\#\{\text{number of sequences}\}} = \frac{\sum_k 1(q_1^k = S_i)}{K} \tag{13.8}$$

where $1(b)$ is 1 if b is true and 0 otherwise.

As for the transition probabilities, the estimate for a_{ij} is the number of transitions from S_i to S_j divided by the total number of transitions from S_i over all sequences:

$$\hat{a}_{ij} = \frac{\#\{\text{transitions from } S_i \text{ to } S_j\}}{\#\{\text{transitions from } S_i\}} = \frac{\sum_k \sum_{t=1}^{T-1} 1(q_t^k = S_i \text{ and } q_{t+1}^k = S_j)}{\sum_k \sum_{t=1}^{T-1} 1(q_t^k = S_i)} \tag{13.9}$$

$\hat{a}_{12}$ is the number of times a blue ball follows a red ball divided by the total number of red ball draws over all sequences.

13.3 Hidden Markov Models

HIDDEN MARKOV MODEL

In a *hidden Markov model* (HMM), the states are not observable, but when we visit a state, an observation is recorded that is a probabilistic function of the state. We assume a discrete observation in each state from the set $\{v_1, v_2, \ldots, v_M\}$:

$$b_j(m) \equiv P(O_t = v_m | q_t = S_j) \tag{13.10}$$

OBSERVATION PROBABILITY
EMISSION PROBABILITY

$b_j(m)$ is the *observation,* or *emission probability* that we observe $v_m, m = 1, \ldots, M$ in state S_j. We again assume a homogeneous model in which the probabilities do not depend on t. The values thus observed constitute the observation sequence O. The state sequence Q is not observed, that is what makes the model "hidden," but it should be inferred from the observation sequence O. Note that there are typically many different state sequences Q that could have generated the same observation sequence O, but with different probabilities; just as, given an iid sample from a normal distribution, there are an infinite number of (μ, σ) value pairs possible, we are interested in the one having the highest likelihood of generating the sample.

Note also that in this case of a hidden Markov model, there are two sources of randomness: Additional to randomly moving from one state to another, the observation in a state is also random.

Let us go back to our example: The hidden case corresponds to the urn-and-ball example where each urn contains balls of different colors. Let $b_j(m)$ denote the probability of drawing a ball of color m from urn j. We again observe a sequence of ball colors but without knowing the sequence of urns from which the balls were drawn. So it is as if now the urns are placed behind a curtain and somebody picks a ball at random from one of the urns and shows us only the ball, without showing us the urn from which it is picked. The ball is returned to the urn to keep the probabilities the same. The number of ball colors may be different from the number of urns. For example, let us say we have three urns and the observation sequence is

$$O = \{\text{red, red, green, blue, yellow}\}$$

In the previous case, knowing the observation (ball color), we knew the state (urn) exactly because there were separate urns for separate colors and each urn contained balls of only one color. The observable model is a special case of the hidden model where $M = N$ and $b_j(m)$ is 1 if $j = m$

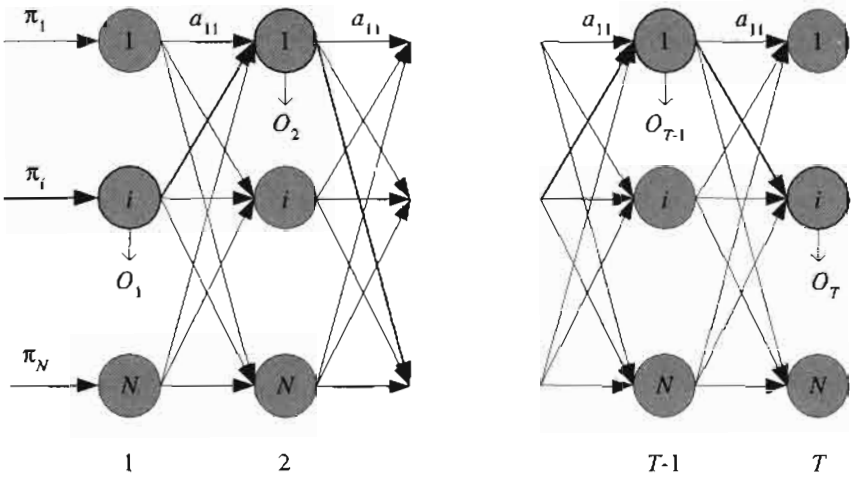

Figure 13.2 An HMM unfolded in time as a lattice (or trellis) showing all the possible trajectories. One path, shown in thicker lines, is the actual (unknown) state trajectory that generated the observation sequence.

and 0 otherwise. But in the case of a hidden model, a ball could have been picked from any urn. In this case, for the same observation sequence O, there may be many possible state sequences Q that could have generated O (see figure 13.2).

To summarize and formalize, an HMM has the following elements:

1. N: Number of states in the model

   $S = \{S_1, S_2, \ldots, S_N\}$

2. M: Number of distinct observation symbols in the *alphabet*

   $V = \{v_1, v_2, \ldots, v_M\}$

3. State transition probabilities:

   $\mathbf{A} = [a_{ij}]$ where $a_{ij} \equiv P(q_{t+1} = S_j | q_t = S_i)$

4. Observation probabilities:

   $\mathbf{B} = [b_j(m)]$ where $b_j(m) \equiv P(O_t = v_m | q_t = S_j)$

5. Initial state probabilities:

$$\mathbf{\Pi} = [\pi_i] \text{ where } \pi_i \equiv P(q_1 = S_i)$$

N and M are implicitly defined in the other parameters so $\lambda = (\mathbf{A}, \mathbf{B}, \mathbf{\Pi})$ is taken as the parameter set of an HMM. Given λ, the model can be used to generate an arbitrary number of observation sequences of arbitrary length, but as usual, we are interested in the other direction, that of estimating the parameters of the model given a training set of sequences.

13.4 Three Basic Problems of HMMs

Given a number of sequences of observations, we are interested in three problems:

1. Given a model λ, we would like to evaluate the probability of any given observation sequence, $O = \{O_1 O_2 \cdots O_T\}$, namely, $P(O|\lambda)$.

2. Given a model λ and an observation sequence O, we would like to find out the state sequence $Q = \{q_1 q_2 \cdots q_T\}$, which has the highest probability of generating O, namely, we want to find Q^* that maximizes $P(Q|O, \lambda)$.

3. Given a training set of observation sequences, $\mathcal{X} = \{O^k\}_k$, we would like to learn the model that maximizes the probability of generating $\mathcal{X}$, namely, we want to find λ^* that maximizes $P(\mathcal{X}|\lambda)$.

Let us see solutions to these one by one, with each solution used to solve the next problem, until we get to calculating λ, or learning a model from data.

13.5 Evaluation Problem

Given an observation sequence $O = \{O_1 O_2 \cdots O_T\}$ and a state sequence $Q = \{q_1 q_2 \cdots q_T\}$, the probability of observing O given the state sequence Q is simply

$$P(O|Q, \lambda) = \prod_{t=1}^{T} P(O_t|q_t, \lambda) = b_{q_1}(O_1) \cdot b_{q_2}(O_2) \cdots b_{q_T}(O_T) \tag{13.11}$$

which we cannot calculate because we do not know the state sequence. The probability of the state sequence Q is

$$P(Q|\lambda) = P(q_1)\prod_{t=2}^{T} P(q_t|q_{t-1}) = \pi_{q_1} a_{q_1 q_2} \cdots a_{q_{T-1} q_T} \tag{13.12}$$

Then the joint probability is

$$\begin{aligned} P(O,Q|\lambda) &= P(q_1)\prod_{t=2}^{T} P(q_t|q_{t-1})\prod_{t=1}^{T} P(O_t|q_t) \\ &= \pi_{q_1} b_{q_1}(O_1) a_{q_1 q_2} b_{q_2}(O_2) \cdots a_{q_{T-1} q_T} b_{q_T}(O_T) \end{aligned} \tag{13.13}$$

We can compute $P(O|\lambda)$ by marginalizing over the joint, namely, by summing up over all possible Q:

$$P(O|\lambda) = \sum_{\text{all possible } Q} P(O,Q|\lambda)$$

However, this is not practical since there are N^T possible Q, assuming that all the probabilities are nonzero. Fortunately, there is an efficient procedure to calculate $P(O|\lambda)$, which is called the *forward-backward procedure.* It is based on the idea of dividing the observation sequence into two parts: the first one starting from time 1 until time t, and the second one from time $t+1$ until T.

FORWARD-BACKWARD PROCEDURE

FORWARD VARIABLE

We define the *forward variable* $\alpha_t(i)$ as the probability of observing the partial sequence $\{O_1 \cdots O_t\}$ until time t and being in S_i at time t, given the model λ:

$$\alpha_t(i) \equiv P(O_1 \cdots O_t, q_t = S_i|\lambda) \tag{13.14}$$

The nice thing about this is that it can be calculated recursively by accumulating results on the way:

- Initialization:

$$\begin{aligned} \alpha_1(i) &\equiv P(O_1, q_1 = S_i|\lambda) \\ &= P(O_1|q_1 = S_i, \lambda)P(q_1 = S_i|\lambda) \\ &= \pi_i b_i(O_1) \end{aligned} \tag{13.15}$$

- Recursion (see figure 13.3(a)):

$$\alpha_{t+1}(j) \equiv P(O_1 \cdots O_{t+1}, q_{t+1} = S_j|\lambda)$$

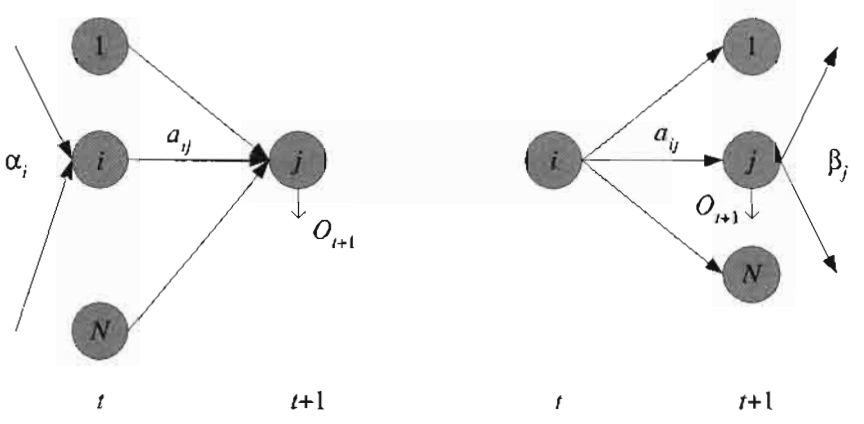

Figure 13.3 Forward-backward procedure: (a) computation of $\alpha_t(j)$ and (b) computation of $\beta_t(i)$.

$$
\begin{aligned}
&= P(O_1 \cdots O_{t+1} | q_{t+1} = S_j, \lambda) P(q_{t+1} = S_j | \lambda) \\
&= P(O_1 \cdots O_t | q_{t+1} = S_j, \lambda) P(O_{t+1} | q_{t+1} = S_j, \lambda) P(q_{t+1} = S_j | \lambda) \\
&= P(O_1 \cdots O_t, q_{t+1} = S_j | \lambda) P(O_{t+1} | q_{t+1} = S_j, \lambda) \\
&= P(O_{t+1} | q_{t+1} = S_j, \lambda) \sum_i P(O_1 \cdots O_t, q_t = S_i, q_{t+1} = S_j | \lambda) \\
&= P(O_{t+1} | q_{t+1} = S_j, \lambda) \\
&\quad \sum_i P(O_1 \cdots O_t, q_{t+1} = S_j | q_t = S_i, \lambda) P(q_t = S_i | \lambda) \\
&= P(O_{t+1} | q_{t+1} = S_j, \lambda) \\
&\quad \sum_i P(O_1 \cdots O_t | q_t = S_i, \lambda) P(q_{t+1} = S_j | q_t = S_i, \lambda) P(q_t = S_i | \lambda) \\
&= P(O_{t+1} | q_{t+1} = S_j, \lambda) \\
&\quad \sum_i P(O_1 \cdots O_t, q_t = S_i | \lambda) P(q_{t+1} = S_j | q_t = S_i, \lambda) \\
&= \left[\sum_{i=1}^{N} \alpha_t(i) a_{ij} \right] b_j(O_{t+1}) \qquad (13.16)
\end{aligned}
$$

$\alpha_t(i)$ explains the first t observations and ends in state S_i. We multiply this by the probability a_{ij} to move to state S_j, and because there are

N possible previous states, we need to sum up over all such possible previous S_i. $b_j(O_{t+1})$ then is the probability we generate the $(t+1)$st observation while in state S_j at time $t+1$.

When we calculate the forward variables, it is easy to calculate the probability of the observation sequence:

$$\begin{aligned} P(O|\lambda) &= \sum_{i=1}^{N} P(O, q_T = S_i|\lambda) \\ &= \sum_{i=1}^{N} \alpha_T(i) \end{aligned} \tag{13.17}$$

$\alpha_T(i)$ is the probability of generating the full observation sequence and ending up in state S_i. We need to sum up over all such possible final states.

Computing $\alpha_t(i)$ is $\mathcal{O}(N^2T)$, and this solves our first evaluation problem in a reasonable amount of time. We do not need it now but let us similarly define the *backward variable*, $\beta_t(i)$, which is the probability of being in S_i at time t and observing the partial sequence $O_{t+1} \cdots O_T$:

BACKWARD VARIABLE

$$\beta_t(i) \equiv P(O_{t+1} \cdots O_T|q_t = S_i, \lambda) \tag{13.18}$$

This can again be recursively computed as follows, this time going in the backward direction:

- Initialization (arbitrarily to 1):

$$\beta_T(i) = 1$$

- Recursion (see figure 13.3(b)):

$$\begin{aligned} \beta_t(i) &\equiv P(O_{t+1} \cdots O_T|q_t = S_i, \lambda) \\ &= \sum_j P(O_{t+1} \cdots O_T, q_{t+1} = S_j|q_t = S_i, \lambda) \\ &= \sum_j P(O_{t+1} \cdots O_T|q_{t+1} = S_j, q_t = S_i, \lambda) P(q_{t+1} = S_j|q_t = S_i, \lambda) \\ &= \sum_j P(O_{t+1}|q_{t+1} = S_j, q_t = S_i, \lambda) \\ &\quad P(O_{t+2} \cdots O_T|q_{t+1} = S_j, q_t = S_i, \lambda) P(q_{t+1} = S_j|q_t = S_i, \lambda) \\ &= \sum_j P(O_{t+1}|q_{t+1} = S_j, \lambda) \end{aligned}$$

$$P(O_{t+2} \cdots O_T | q_{t+1} = S_j, \lambda) P(q_{t+1} = S_j | q_t = S_i, \lambda)$$

$$= \sum_{j=1}^{N} a_{ij} b_j(O_{t+1}) \beta_{t+1}(j) \tag{13.19}$$

When in state S_i, we can go to N possible next states S_j, each with probability a_{ij}. While there, we generate the $(t+1)$st observation and $\beta_{t+1}(j)$ explains all the observations after time $t+1$, continuing from there.

One word of caution about implementation is necessary here: Both α_t and β_t values are calculated by multiplying small probabilities, and with long sequences we risk getting underflow. To avoid this, at each time step, we normalize $\alpha_t(i)$ by dividing it with $c_t = \sum_j \alpha_t(j)$. We also normalize $\beta_t(i)$ by dividing it with the same c_t ($\beta_t(i)$ do not sum to 1).

13.6 Finding the State Sequence

We now move on to the second problem, that of finding the state sequence $Q = \{q_1 q_2 \cdots q_T\}$ having the highest probability of generating the observation sequence $O = \{O_1 O_2 \cdots O_T\}$, given the model λ.

Let us define $\gamma_t(i)$ as the probability of being in state S_i at time t, given O and λ, which can be computed as

$$\begin{aligned}
\gamma_t(i) &\equiv P(q_t = S_i | O, \lambda) \\
&= \frac{P(O | q_t = S_i, \lambda) P(q_t = S_i | \lambda)}{P(O | \lambda)} \\
&= \frac{P(O_1 \cdots O_t | q_t = S_i, \lambda) P(O_{t+1} \cdots O_T | q_t = S_i, \lambda) P(q_t = S_i | \lambda)}{\sum_{j=1}^{N} P(O, q_t = S_j | \lambda)} \\
&= \frac{P(O_1 \cdots O_t, q_t = S_i | \lambda) P(O_{t+1} \cdots O_T | q_t = S_i, \lambda)}{\sum_{j=1}^{N} P(O | q_t = S_j, \lambda) P(q_t = S_j | \lambda)} \\
&= \frac{\alpha_t(i) \beta_t(i)}{\sum_{j=1}^{N} \alpha_t(j) \beta_t(j)} \qquad (13.21)
\end{aligned} \tag{13.20}$$

Here we see how nicely $\alpha_t(i)$ and $\beta_t(i)$ split the sequence between them: The forward variable $\alpha_t(i)$ explains the starting part of the sequence until time t and ends in S_i, and the backward variable $\beta_t(i)$ takes it from there and explains the ending part until time T.

The numerator $\alpha_t(i)\beta_t(i)$ explains the whole sequence given that at time t, the system is in state S_i. We need to normalize by dividing this

over all possible intermediate states that can be traversed at time t, and guarantee that $\sum_i \gamma_t(i) = 1$.

To find the state sequence, for each time step t, we can choose the state that has the highest probability:

$$q_t^* = \arg\max_i \gamma_t(i) \tag{13.22}$$

but this may choose S_i and S_j as the most probable states at time t and $t+1$ even when $a_{ij} = 0$. To find the single best state *sequence* (path), we use the *Viterbi algorithm*, based on dynamic programming, which takes such transition probabilities into account.

VITERBI ALGORITHM

Given state sequence $Q = q_1 q_2 \cdots q_T$ and observation sequence $O = O_1 \cdots O_T$, we define $\delta_t(i)$ as the probability of the highest probability path at time t that accounts for the first t observations and ends in S_i:

$$\delta_t(i) \equiv \max_{q_1 q_2 \cdots q_{t-1}} p(q_1 q_2 \cdots q_{t-1}, q_t = S_i, O_1 \cdots O_t | \lambda) \tag{13.23}$$

Then we can recursively calculate $\delta_{t+1}(i)$ and the optimal path can be read by backtracking from T, choosing the most probable at each instant. The algorithm is as follows:

1. Initialization:

$$\begin{aligned} \delta_1(i) &= \pi_i b_i(O_1) \\ \psi_1(i) &= 0 \end{aligned}$$

2. Recursion:

$$\begin{aligned} \delta_t(j) &= \max_i \delta_{t-1}(i) a_{ij} \cdot b_j(O_t) \\ \psi_t(j) &= \arg\max_i \delta_{t-1}(i) a_{ij} \end{aligned}$$

3. Termination:

$$\begin{aligned} p^* &= \max_i \delta_T(i) \\ q_T^* &= \arg\max_i \delta_T(i) \end{aligned}$$

4. Path (state sequence) backtracking:

$$q_t^* = \psi_{t+1}(q_{t+1}^*), \; t = T-1, T-2, \ldots, 1$$

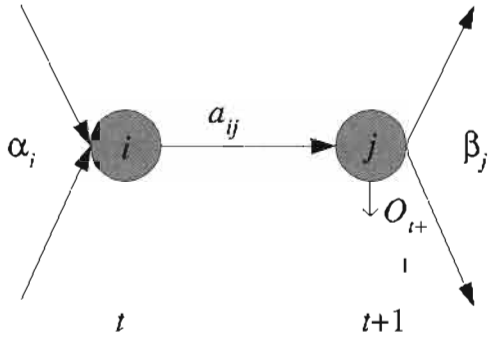

Figure 13.4 Computation of arc probabilities, $\xi_t(i,j)$.

Using the lattice structure of figure 13.2, $\psi_t(j)$ keeps track of the state that maximizes $\delta_t(j)$ at time $t-1$, that is, the best previous state. The Viterbi algorithm has the same complexity with the forward phase, where instead of the sum, we take the maximum at each step.

13.7 Learning Model Parameters

We now move on to the third problem, learning an HMM from data. The approach is maximum likelihood, and we would like to calculate λ^* that maximizes the likelihood of the sample of training sequences, $\mathcal{X} = \{O^k\}_{k=1}^K$, namely, $P(\mathcal{X}|\lambda)$. We start by defining a new variable that will become handy later on.

We define $\xi_t(i,j)$ as the probability of being in S_i at time t and in S_j at time $t+1$, given the whole observation O and λ:

(13.24) $$\xi_t(i,j) \equiv P(q_t = S_i, q_{t+1} = S_j | O, \lambda)$$

which can be computed as (see figure 13.4)

$$\begin{aligned}
\xi_t(i,j) &\equiv P(q_t = S_i, q_{t+1} = S_j | O, \lambda) \\
&= \frac{P(O|q_t = S_i, q_{t+1} = S_j, \lambda) P(q_t = S_i, q_{t+1} = S_j | \lambda)}{P(O|\lambda)} \\
&= \frac{P(O|q_t = S_i, q_{t+1} = S_j, \lambda) P(q_{t+1} = S_j | q_t = S_i, \lambda) P(q_t = S_i | \lambda)}{P(O|\lambda)}
\end{aligned}$$

$$
\begin{aligned}
&= \left(\frac{1}{P(O|\lambda)}\right) P(O_1 \cdots O_t | q_t = S_i, \lambda) P(O_{t+1} | q_{t+1} = S_j, \lambda) \\
&\quad P(O_{t+2} \cdots O_T | q_{t+1} = S_j, \lambda) a_{ij} P(q_t = S_i | \lambda) \\
&= \left(\frac{1}{P(O|\lambda)}\right) P(O_1 \cdots O_t, q_t = S_i | \lambda) P(O_{t+1} | q_{t+1} = S_j, \lambda) \\
&\quad P(O_{t+2} \cdots O_T | q_{t+1} = S_j, \lambda) a_{ij} \\
&= \frac{\alpha_t(i) b_j(O_{t+1}) \beta_{t+1}(j) a_{ij}}{\sum_k \sum_l P(q_t = S_k, q_{t+1} = S_l, O|\lambda)} \\
&= \frac{\alpha_t(i) a_{ij} b_j(O_{t+1}) \beta_{t+1}(j)}{\sum_k \sum_l \alpha_t(k) a_{kl} b_l(O_{t+1}) \beta_{t+1}(l)}
\end{aligned} \tag{13.25}
$$

$\alpha_t(i)$ explains the first t observations and ends in state S_i at time t. We move on to state S_j with probability a_{ij}, generate the $(t+1)$st observation, and continue from S_j at time $t+1$ to generate the rest of the observation sequence. We normalize by dividing for all such possible pairs that can be visited at time t and $t+1$.

If we want, we can also calculate the probability of being in state S_i at time t by marginalizing over the arc probabilities for all possible next states:

$$
\gamma_t(i) = \sum_{j=1}^{N} \xi_t(i,j) \tag{13.26}
$$

Note that if the Markov model were not hidden but observable, both $\gamma_t(i)$ and $\xi_t(i,j)$ would be 0/1. In this case when they are not, we estimate them with posterior probabilities that give us *soft counts*. This is just like the difference between supervised classification and unsupervised clustering where we did and did not know the class labels respectively. In unsupervised clustering using EM (section 7.4), not knowing the class labels, we estimated them first (in the E-step) and calculated the parameters with these estimates (in the M-step).

SOFT COUNTS

BAUM-WELCH ALGORITHM

Similarly here we have the *Baum-Welch algorithm*, which is an EM procedure. At each iteration, first in the E-step, we compute $\xi_t(i,j)$ and $\gamma_t(i)$ values given the current $\lambda = (\mathbf{A}, \mathbf{B}, \mathbf{\Pi})$, and then in the M-step, we recalculate λ given $\xi_t(i,j)$ and $\gamma_t(i)$. These two steps are alternated until convergence during which, it has been shown that, $P(O|\lambda)$ never decreases.

Assume indicator variables z_i^t as

$$
z_i^t = \begin{cases} 1 & \text{if } q_t = S_i \\ 0 & \text{otherwise} \end{cases} \tag{13.27}
$$

and

$$z_{ij}^t = \begin{cases} 1 & \text{if } q_t = S_i \text{ and } q_{t+1} = S_j \\ 0 & \text{otherwise} \end{cases} \tag{13.28}$$

These are 0/1 in the case of an observable Markov model and are hidden random variables in the case of an HMM. In this latter case, we estimate them in the E-step as

$$\begin{aligned} E[z_i^t] &= \gamma_t(i) \\ E[z_{ij}^t] &= \xi_t(i,j) \end{aligned} \tag{13.29}$$

In the M-step, we calculate the parameters given these estimated values. The expected number of transitions from S_i to S_j is $\sum_t \xi_t(i,j)$ and the total number of transitions from S_i is $\sum_t \gamma_t(i)$. The ratio of these two gives us the probability of transition from S_i to S_j at any time:

$$\hat{a}_{ij} = \frac{\sum_{t=1}^{T-1} \xi_t(i,j)}{\sum_{t=1}^{T-1} \gamma_t(i)} \tag{13.30}$$

Note that this is the same as equation 13.9, except that the actual counts are replaced by estimated soft counts.

The probability of observing v_m in S_j is the expected number of times v_m is observed when the system is in S_j over the total number of times the system is in S_j:

$$\hat{b}_j(m) = \frac{\sum_{t=1}^{T} \gamma_t(j) 1(O_t = v_m)}{\sum_{t=1}^{T} \gamma_t(j)} \tag{13.31}$$

When there are multiple observation sequences

$$\mathcal{X} = \{O^k\}_{k=1}^K$$

which we assume to be independent

$$P(\mathcal{X}|\lambda) = \prod_{k=1}^{K} P(O^k|\lambda)$$

the parameters are now averages over all observations in all sequences:

$$\begin{aligned} \hat{a}_{ij} &= \frac{\sum_{k=1}^{K} \sum_{t=1}^{T_k-1} \xi_t^k(i,j)}{\sum_{k=1}^{K} \sum_{t=1}^{T_k-1} \gamma_t^k(i)} \\ \hat{b}_j(m) &= \frac{\sum_{k=1}^{K} \sum_{t=1}^{T_k-1} \gamma_t^k(j) 1(O_t^k = v_m)}{\sum_{k=1}^{K} \sum_{t=1}^{T_k-1} \gamma_t^k(j)} \\ \hat{\pi}_i &= \frac{\sum_{k=1}^{K} \gamma_1^k(i)}{K} \end{aligned} \tag{13.32}$$

13.8 Continuous Observations

In our discussion, we assumed discrete observations modeled as a multinomial

$$P(O_t|q_t = S_j, \lambda) = \prod_{m=1}^{M} b_j(m)^{r_m^t} \tag{13.33}$$

where

$$r_m^t = \begin{cases} 1 & \text{if } O_t = v_m \\ 0 & \text{otherwise} \end{cases} \tag{13.34}$$

If the inputs are continuous, one possibility is to discretize them and then use these discrete values as observations. Typically, a vector quantizer (section 7.3) is used for this purpose of converting continuous values to the discrete index of the closest reference vector. For example, in speech recognition, a word utterance is divided into short speech segments corresponding to phonemes or part of phonemes; after preprocessing, these are discretized using a vector quantizer and an HMM is then used to model a word utterance as a sequence of them.

We remember that k-means used for vector quantization is the hard version of a Gaussian mixture model:

$$p(O_t|q_t = S_j, \lambda) = \sum_{l=1}^{L} P(\mathcal{G}_{jl}) p(O_t|q_t = S_j, \mathcal{G}_l, \lambda) \tag{13.35}$$

where

$$p(O_t|q_t = S_j, \mathcal{G}_l, \lambda) \sim \mathcal{N}(\boldsymbol{\mu}_l, \boldsymbol{\Sigma}_l) \tag{13.36}$$

and the observations are kept continuous. In this case of Gaussian mixtures, EM equations can be derived for the component parameters (with suitable regularization to keep the number of parameters in check) and the mixture proportions (Rabiner 1989).

Let us see the case of a scalar continuous observation, $O_t \in \Re$. The easiest is to assume a normal distribution:

$$p(O_t|q_t = S_j, \lambda) \sim \mathcal{N}(\mu_j, \sigma_j^2) \tag{13.37}$$

which implies that in state S_j, the observation is drawn from a normal with mean μ_j and variance σ_j^2. The M-step equations in this case are

$$\hat{\mu}_j = \frac{\sum_t \gamma_t(j) O_t}{\sum_t \gamma_t(j)} \tag{13.38}$$

$$\hat{\sigma}_j^2 = \frac{\sum_t \gamma_t(j)(O_t - \hat{\mu}_j)^2}{\sum_t \gamma_t(j)}$$

13.9 The HMM with Input

In some applications, additional to the observation sequence O_t, we have an input sequence, x_t. We can condition the observation O_t in state S_j on the input x^t, and write $P(O_t|q_t = S_j, x_t)$. In the case when the observations are continuous scalars, we replace equation 13.37 with a generalized model

$$p(O_t|q_t = S_j, x_t, \lambda) \sim \mathcal{N}(g_j(x^t|\theta_j), \sigma_j^2) \tag{13.39}$$

where, for example, assuming a linear model, we have

$$g_j(x^t|w_j, w_{j0}) = w_j x^t + w_{j0} \tag{13.40}$$

If the observations are discrete and multinomial, we have a classifier taking x^t as input and generating a 1-of-M output, or we can generate posterior class probabilities and keep the observations continuous.

Similarly, the state transition probabilities can also be conditioned on the input, namely, $P(q_{t+1} = S_j|q_t = S_i, x_t)$, which is implemented by a classifier choosing the state at time $t+1$ as a function of the state at time t and the input. This is a *Markov mixture of experts* (Meila and Jordan 1996) and is a generalization of the mixture of experts architecture (section 12.8) where the gating network keeps track of the decision it made in the previous time step. Such an architecture is also called an *input-output HMM* (Bengio and Frasconi 1996) and has the advantage that the model is no longer homogeneous; different observation and transition probabilities are used at different time steps. There is still a single model for each state, parameterized by θ_j, but it generates different transition or observation probabilities depending on the input seen. It is possible that the input is not a single value but a window around time t making the input a vector; this allows handling applications where the input and observation sequences have different lengths.

MARKOV MIXTURE OF EXPERTS

INPUT-OUTPUT HMM

Even if there is no other explicit input sequence, an HMM with input can be used by generating an "input" through some prespecified function of previous observations

$$\mathbf{x}_t = \mathbf{f}(O_{t-\tau}, \ldots, O_{t-1})$$

thereby providing a window of size τ of contextual input.

13.10 Model Selection in HMM

Just like any model, the complexity of an HMM should be tuned so as to balance its complexity with the size and properties of the data at hand. One possibility is to tune the topology of the HMM. In a fully connected (ergodic) HMM, there is transition from a state to any other state, which makes $\mathbf{A}$ a full $N \times N$ matrix. In some applications, only certain transitions are allowed, with the disallowed transitions having their $a_{ij} = 0$. When there are fewer possible next states, $N' < N$, the complexity of forward-backward passes and the Viterbi procedure is $\mathcal{O}(NN'T)$ instead of $\mathcal{O}(N^2T)$.

LEFT-TO-RIGHT HMMs

For example, in speech recognition, *left-to-right HMMs* are used, which have their states ordered in time so that as time increases, the state index increases or stays the same. Such a constraint allows modeling sequences whose properties change over time as in speech, and when we get to a state, we know approximately the states preceding it. There is the property that we never move to a state with a smaller index, namely, $a_{ij} = 0, \text{for } j < i$. Large changes in state indices are not allowed either, namely, $a_{ij} = 0, \text{for } j > i + \tau$. The example of the left-to-right HMM given in figure 13.5 with $\tau = 2$ has the state transition matrix

$$\mathbf{A} = \begin{bmatrix} a_{11} & a_{12} & a_{13} & 0 \\ 0 & a_{22} & a_{23} & a_{24} \\ 0 & 0 & a_{33} & a_{34} \\ 0 & 0 & 0 & a_{44} \end{bmatrix}$$

Another factor that determines the complexity of an HMM is the number of states N. Because the states are hidden, their number is not known and should be chosen before training. This is determined using prior information and can be fine-tuned by cross-validation, namely, by checking the likelihood of validation sequences.

When used for classification, we have a set of HMMs, each one modeling the sequences belonging to one class. For example, in spoken word recognition, examples of each word train a separate model, λ_i. Given a new word utterance O to classify, all of the separate word models are evaluated to calculate $P(O|\lambda_i)$. We then use Bayes' rule to get the posterior probabilities

$$P(\lambda_i|O) = \frac{P(O|\lambda_i)P(\lambda_i)}{\sum_j P(O|\lambda_j)P(\lambda_j)} \tag{13.41}$$

where $P(\lambda_i)$ is the prior probability of word i. The utterance is assigned

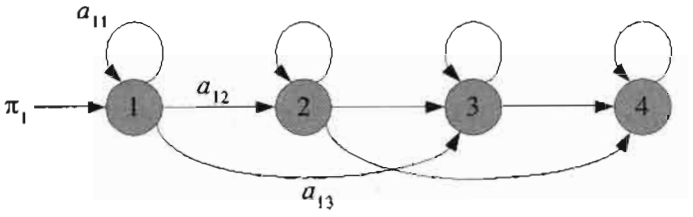

Figure 13.5 Example of a left-to-right HMM.

to the word having the highest posterior. This is the likelihood-based approach; there is also work on discriminative HMM trained directly to maximize the posterior probabilities. When there are several pronunciations of the same word, these are defined as parallel paths in the HMM for the word.

PHONES

In the case of a continuous input like speech, the difficult task is that of segmenting the signal into small discrete observations. Typically, *phones* are used that are taken as the primitive parts, and combining them, longer sequences (e.g., words) are formed. Each phone is recognized in parallel (by the vector quantizer), then the HMM is used to combine them serially. If the speech primitives are simple, then the HMM becomes complex and vice versa. In connected speech recognition where the words are not uttered one by one with clear pauses between them, there is a hierarchy of HMMs at several levels; one combines phones to recognize words, another combines words to recognize sentences by building a language model, and so forth.

In recent years, hybrid neural network/HMM models became popular for speech recognition (Morgan and Bourlard 1995). In such a model, a multilayer perceptron (chapter 11) is used to capture temporally local but possibly complex and nonlinear primitives, for example, phones, while the HMM is used to learn the temporal structure. The neural network acts as a preprocessor and translates the raw observations in a time window to a form that is easier to model than the output of a vector quantizer.

13.11 Notes

The HMM is a mature technology, and there are HMM-based commercial speech recognition systems in actual use (Rabiner and Juang 1993;

Jelinek 1997). In section 11.12, we discussed how to train multilayer perceptrons for recognizing sequences. HMMs have the advantage over time delay neural networks in that no time window needs to be defined a priori, and they train better than recurrent neural networks. HMMs are applied to diverse sequence recognition tasks. Applications of HMMs to bioinformatics is given in Baldi and Brunak 1998, and to natural language processing in Manning and Schütze 1999. It is also applied to online handwritten character recognition, which differs from optical recognition in that the writer writes on a touch-sensitive pad and the input is a sequence of (x, y) coordinates of the pen tip as it moves over the pad and is not a static image. Bengio et al. (1995) explain a hybrid system for online recognition where an MLP recognizes individual characters, and an HMM combines them to recognize words.

In any such recognition system, one critical point is to decide how much to do things in parallel and what to leave to serial processing. In speech recognition, phonemes may be recognized by a parallel system that corresponds to assuming that all the phoneme sound is uttered in one time step. The word is then recognized serially by combining the phonemes. In an alternative system, phonemes themselves may be designed as a sequence of simpler speech sounds, if the same phoneme has many versions, for example, depending on the previous and following phonemes. Doing things in parallel is good but only to a degree; one should find the ideal balance of parallel and serial processing. To be able to call anyone at the touch of a button, we would need millions of buttons on our telephone; instead, we have ten buttons and we press them in a sequence to dial the number.

Various applications of the HMM and several extensions, for example, discriminative HMMs, are discussed in Bengio 1999. An HMM can be written as a Bayesian network (section 3.7), and inference and learning operations on HMMs are analogous to their counterparts in Bayesian networks (Smyth, Heckerman, and Jordan 1997). There are various recently proposed extensions to HMMs like factorial HMMs where at each time step, there are a number of states that collectively generate the observation and tree-structured HMMs where there is a hierarchy of states. These extensions and the approximation methods for training them are discussed in the tutorial paper by Ghahramani (2001).

13.12 Exercises

1. Given the observable Markov model with three states, S_1, S_2, S_3, initial probabilities

   $\mathbf{\Pi} = [0.5, 0.2, 0.3]^T$

   and transition probabilities

   $$\mathbf{A} = \begin{bmatrix} 0.4 & 0.3 & 0.3 \\ 0.2 & 0.6 & 0.2 \\ 0.1 & 0.1 & 0.8 \end{bmatrix}$$

   generate 100 sequences of 1,000 states.
2. Using the data generated by the previous exercise, estimate Π, $\mathbf{A}$ and compare with the parameters used to generate the data.
3. Formalize a second-order Markov model. What are the parameters? How can we calculate the probability of a given state sequence? How can the parameters be learned for the case of a observable model?
4. Show that any second- (or higher-order) Markov model can be converted to a first-order Markov model.
5. Some researchers define a Markov model as generating an observation while traversing an arc, instead of on arrival to a state. Is this model any more powerful than what we have discussed?
6. Generate training and validation sequences from an HMM of your choosing. Then train different HMMs by varying the number of hidden states on the same training set and calculate the validation likelihoods. Observe how the validation likelihood changes as the number of states increases.

14 Assessing and Comparing Classification Algorithms

Machine learning algorithms induce classifiers that depend on the training set, and there is a need for statistical testing to (i) assess the expected error rate of a classification algorithm, and (ii) compare the expected error rates of two classification algorithms to be able to say which one is better. We review hypothesis testing and discuss tests for error rate assessment and comparison.

14.1 Introduction

IN PREVIOUS chapters, we discussed several classification algorithms and learned that, given a certain application, more than one is applicable. Now, we are concerned with two questions:

1. How can we assess the expected error rate of a classification algorithm on a problem? That is, having used a classification algorithm to train a classifier, can we say with enough confidence that later on when it is used in real life, its expected error rate will be less than, for example, 2 percent?

2. Given two classification algorithms, how can we say one has less error than the other one, for a given application? The classification algorithms compared can be different, for example, parametric versus nonparametric, or they can use different hyperparameter settings. For example, given a multilayer perceptron (chapter 11) with four hidden units and another one with eight hidden units, we would like to be able say which one has less expected error. Or with the k-nearest neighbor classifier (chapter 8), we would like to find the best value of k.

We cannot look at the training set errors and decide based on those. The error rate on the training set, by definition, is always smaller than the error rate on a test set containing instances unseen during training. Similarly, training errors cannot be used to compare two algorithms. This is because over the training set, the more complex model having more parameters will almost always give fewer errors than the simple one.

So as we have repeatedly discussed, we need a validation set different from the training set. Even over a validation set though, just one run may not be enough. There are two reasons for this: First, the training and validation sets may be small and may contain exceptional instances, like noise and outliers, which may mislead us. The second reason is that the learning method may depend on other random factors affecting generalization. For example, with a multilayer perceptron trained using backpropagation, because gradient descent converges to the nearest local minimum, the initial weights affect the final weights, and given the exact same architecture and training set, starting from different initial weights, there may be multiple possible final classifiers having different error rates on the same validation set. We thus would like to have several runs to average over such sources of randomness. If we train and validate only once, we can not test for the effect of such factors; this is only admissible if the learning method is so costly that it can be trained and validated only once.

We use a *classification algorithm* on a dataset and generate a *classifier*. If we do the training once, we have one classifier and one validation error. To average over randomness (in training data, initial weights, etc.), we use the same algorithm and generate multiple classifiers. We test these classifiers on multiple validation sets and record a sample of validation errors. (Of course, all the training and validation sets should be drawn from the same application.) We base our evaluation of the classification algorithm on the *distribution* of these validation errors. We can use this distribution for assessing the *expected error rate* of the classification algorithm for that problem, or compare it with the error rate distribution of some other classification algorithm.

EXPECTED ERROR RATE

Before proceeding to how this is done, it is important to stress a number of points:

1. We should keep in mind that whatever conclusion we draw from our analysis is conditioned on the dataset we are given. We are not comparing classification algorithms in a domain independent way but on

some particular application. We are not saying anything about the expected error rate of a learning algorithm, or comparing one learning algorithm with another algorithm, in general. Any result we have is only true for the particular application, and only insofar as that application is represented in the sample we have. And anyway, there is no such thing as the "best" learning algorithm. For any learning algorithm, there is a dataset where it is very accurate and another dataset where it is very poor. When we say a classification algorithm is good, we only quantify how well its inductive bias matches the properties of the data. This is called the *No Free Lunch Theorem* (Wolpert 1995).

NO FREE LUNCH THEOREM

2. The division of a given dataset into a number of training and validation set pairs is only for testing purposes. Once all the tests are complete and we have made our decision as to the final method or hyperparameters, to train the final classifier, we can use all the labeled data that we have previously used for training or validation.

3. Because we also use the validation set(s) for testing purposes, for example, for choosing the better of two classification algorithms, or to decide where to stop learning, it effectively becomes part of the data we use. When after all such tests, we decide on a particular classification algorithm and want to report its expected error rate, we should use a separate *test set* for this purpose, unused during training this final system. This data should have never been used before for training or validation and should be large for the error estimate to be meaningful. So, given a dataset, we should first leave some part of it aside as the test set and use the rest for training and validation. Typically, we can leave one-third of the sample as the test set, then use the two-thirds for cross-validation to generate multiple training/validation set pairs, as we see in the next section. So, the training set is used to optimize the parameters, given a particular learning algorithm and model structure; the validation set is used to optimize the hyperparameters of the learning algorithm or the model structure; and the test set is used at the end, once both these have been optimized. For example, with an MLP, the training set is used to optimize the weights, the validation set is used to decide on the number of hidden units, how long to train, the learning rate, and so forth. Once the best MLP configuration is chosen, its final error rate is calculated on the test set. With k-NN, the training set is stored as the lookup table; we optimize the

distance measure and k on the validation set and test finally on the test set.

4. In this chapter, we compare classification algorithms by their error rates, but it should be kept in mind that in real life, error is only one of the criteria that affect our decision. Some other criteria are (Turney 2000):
   - risks when errors are generalized using loss functions, instead of 0/1 loss (section 3.3),
   - training time and space complexity,
   - testing time and space complexity,
   - interpretability, namely, whether the method allows knowledge extraction which can be checked and validated by experts, and
   - easy programmability.

   The relative importances of these factors change depending on the application. For example, if the training is to be done once in the factory, than training time and space complexity are not important; if adaptability during use is required, then they do become important. Most of the learning algorithms use 0/1 loss and take error as the single criterion to be minimized; recently *cost-sensitive learning* variants of these algorithms have also been proposed to take other cost criteria into account.

COST-SENSITIVE LEARNING

14.2 Cross-Validation and Resampling Methods

Our first need is to get a number of training/validation set pairs from a dataset $\mathcal{X}$. To get them, if the sample $\mathcal{X}$ is large enough, we can randomly divide it into K parts, then divide each part randomly into two and use one half for training and the other half for validation. K is typically 10 or 30. Unfortunately, datasets are never large enough to do this. So we should do our best with small datasets. This is done by repeated use of the same data split differently; this is called *cross-validation.* The catch is that this makes the error percentages dependent as these different sets share data.

CROSS-VALIDATION

So, given a dataset $\mathcal{X}$, we would like to generate K training/validation set pairs, $\{\mathcal{T}_i, \mathcal{V}_i\}_{i=1}^{K}$, from this dataset. We would like to keep the training and validation sets as large as possible so that the error estimates

are robust, and at the same time, we would like to keep the overlap between different sets as small as possible. We also need to make sure that classes are represented in the right proportions when subsets of data are held out, not to disturb the class prior probabilities; this is called *stratification:* If a class has 20 percent examples in the whole dataset, in all samples drawn from the dataset, it should also have approximately 20 percent examples.

STRATIFICATION

14.2.1 K-Fold Cross-Validation

K-FOLD CROSS-VALIDATION

In *K-fold cross-validation,* the dataset $\mathcal{X}$ is divided randomly into K equal-sized parts, $\mathcal{X}_i, i = 1, \ldots, K$. To generate each pair, we keep one of the K parts out as the validation set, and combine the remaining $K - 1$ parts to form the training set. Doing this K times, each time leaving out another one of the K parts out, we get K pairs:

$$\begin{aligned}
\mathcal{V}_1 &= \mathcal{X}_1 \quad \mathcal{T}_1 = \mathcal{X}_2 \cup \mathcal{X}_3 \cup \cdots \cup \mathcal{X}_K \\
\mathcal{V}_2 &= \mathcal{X}_2 \quad \mathcal{T}_2 = \mathcal{X}_1 \cup \mathcal{X}_3 \cup \cdots \cup \mathcal{X}_K \\
&\vdots \\
\mathcal{V}_K &= \mathcal{X}_K \quad \mathcal{T}_K = \mathcal{X}_1 \cup \mathcal{X}_2 \cup \cdots \cup \mathcal{X}_{K-1}
\end{aligned}$$

There are two problems with this: First, to keep the training set large, we allow validation sets that are small. Second, the training sets overlap considerably, namely, any two training sets share $K - 2$ parts.

K is typically 10 or 30. As K increases, the percentage of training instances increases and we get more robust estimators, but the validation set becomes smaller. Furthermore, there is the cost of training the classifier K times, which increases as K is increased. As N increases, K can be smaller; if N is small, K should be large to allow large enough training sets. One extreme case of K-fold cross-validation is *leave-one-out* where given a dataset of N instances, only one instance is left out as the validation set (instance) and training uses the $N - 1$ instances. We then get N separate pairs by leaving out a different instance at each iteration. This is typically used in applications such as medical diagnosis, where labeled data is hard to find. Leave-one-out does not permit stratification.

LEAVE-ONE-OUT

14.2.2 5×2 Cross-Validation

5×2 CROSS-VALIDATION

Dietterich (1998) proposed the 5×2 *cross-validation,* which uses training

and validation sets of equal size. We divide the dataset $\mathcal{X}$ randomly into two parts: $\mathcal{X}_1^{(1)}$ and $\mathcal{X}_1^{(2)}$, which gives our first pair of training and validation sets: $\mathcal{T}_1 = \mathcal{X}_1^{(1)}$ and $\mathcal{V}_1 = \mathcal{X}_1^{(2)}$. Then we swap the role of the two halves and get the second pair: $\mathcal{T}_2 = \mathcal{X}_1^{(2)}$ and $\mathcal{V}_2 = \mathcal{X}_1^{(1)}$. This is the first fold; $\mathcal{X}_i^{(j)}$ denotes half j of fold i.

To get the second fold, we shuffle $\mathcal{X}$ randomly and divide this new fold into two, $\mathcal{X}_2^{(1)}$ and $\mathcal{X}_2^{(2)}$. This can be implemented by drawing these from $\mathcal{X}$ randomly without replacement, namely, $\mathcal{X}_1^{(1)} \cup \mathcal{X}_1^{(2)} = \mathcal{X}_2^{(1)} \cup \mathcal{X}_2^{(2)} = \mathcal{X}$. We then swap these two halves to get another pair. We do this for three more folds and because from each fold, we get two pairs, doing five folds, we get ten training and validation sets:

$$
\begin{array}{ll}
\mathcal{T}_1 = \mathcal{X}_1^{(1)} & \mathcal{V}_1 = \mathcal{X}_1^{(2)} \\
\mathcal{T}_2 = \mathcal{X}_1^{(2)} & \mathcal{V}_2 = \mathcal{X}_1^{(1)} \\
\mathcal{T}_3 = \mathcal{X}_2^{(1)} & \mathcal{V}_3 = \mathcal{X}_2^{(2)} \\
\mathcal{T}_4 = \mathcal{X}_2^{(2)} & \mathcal{V}_4 = \mathcal{X}_2^{(1)} \\
\quad \vdots & \\
\mathcal{T}_9 = \mathcal{X}_5^{(1)} & \mathcal{V}_9 = \mathcal{X}_5^{(2)} \\
\mathcal{T}_{10} = \mathcal{X}_5^{(2)} & \mathcal{V}_{10} = \mathcal{X}_5^{(1)}
\end{array}
$$

Of course, we can do this for more than five folds and get more training/validation sets but Dietterich (1998) points out that after five folds, the sets share many instances and overlap so much that the statistics calculated from these sets, namely, validation error rates, become too dependent and do not add new information. Even with five folds, the sets overlap and the statistics are dependent, but we can get away with this until five folds. On the other hand, if we do have fewer than five folds, we get fewer data (fewer than ten) and will not have a large enough sample to fit a distribution to and test our hypothesis on.

14.2.3 Bootstrapping

BOOTSTRAP

To generate multiple samples from a single sample, an alternative to cross-validation is the *bootstrap* that generates new samples by drawing instances from the original sample *with* replacement. The bootstrap samples may overlap more than cross-validation samples and hence their estimates are more dependent; but is considered the best way for very small datasets.

Table 14.1 Confusion matrix

	Predicted class	
True Class	Yes	No
Yes	TP: True Positive	FN: False Negative
No	FP: False Positive	TN: True Negative

In the bootstrap, we sample N instances from a dataset of size N with replacement. If we validate once, the original dataset is used as the validation set; otherwise we can do this many times to generate multiple training/validation sets. The probability that we pick an instance is $1/N$; the probability that we do not pick it is $1 - 1/N$. The probability that we do not pick it after N draws is

$$\left(1 - \frac{1}{N}\right)^N \approx e^{-1} = 0.368$$

This means that the training data contains approximately 63.2 percent of the instances; that is, the system will not have been trained on 36.8 percent of the data, and the error estimate will be pessimistic. The solution is to repeat the process many times and take an average.

14.3 Measuring Error

CONFUSION MATRIX

When 0/1 loss is used, all errors are equally bad, and our error calculations are based on the *confusion matrix* (table 14.1). We can then define error rate as

$$\text{error rate} = \frac{|FN| + |FP|}{N} \tag{14.1}$$

where $N = |TP| + |FP| + |TN| + |FN|$ is the total number of instances in the validation set. In the general case of an arbitrary loss function, this should be replaced by risk on the validation set (section 3.3).

CLASS CONFUSION MATRIX

To analyze errors in the case of $K > 2$ classes, a *class confusion matrix* is useful. It is a $K \times K$ matrix such that its entry (i, j) contains the number of instances that belong to C_i but are assigned to C_j. Ideally, all off-diagonals should be 0, for no misclassification. The class confusion matrix allows us to pinpoint what types of misclassification occur, namely, if there are two classes that are frequently confused.

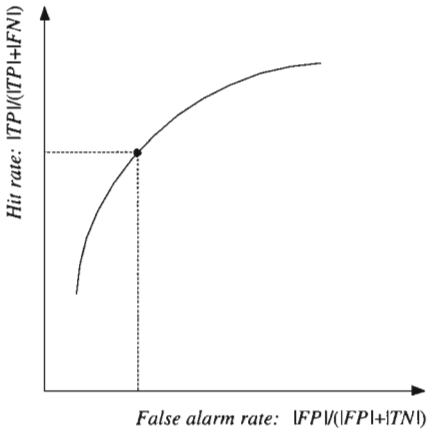

Figure 14.1 Typical roc curve. Each classifier has a parameter, for example, a threshold, which allows us to move over this curve, and we decide on a point, based on the relative importance of hits versus false alarms, namely, true positives and false positives.

RECEIVER OPERATING CHARACTERISTICS

To fine-tune a classifier, another approach is to draw the *receiver operating characteristics* (ROC) curve, which shows hit rate versus false alarm rate, namely, $|TP|/(|TP| + |FN|)$ vs $|FP|/(|FP| + |TN|)$, and has a form similar to figure 14.1. With each classification algorithm, there is a parameter, for example, a threshold of decision, which we can play with to change the number of true positives versus false positives. Increasing the number of true positives also increases the number of false alarms; decreasing the number of false alarms also decreases the number of hits. Depending on how good/costly these are for the particular application we have, we decide on a point on this curve.

14.4 Interval Estimation

INTERVAL ESTIMATION

Let us now do a quick review of *interval estimation* that we will use in hypothesis testing. A point estimator, for example, the maximum likelihood estimator, specifies a value for a parameter θ. In interval estimation, we specify an interval within which θ lies with a certain degree of confidence. To obtain such an interval estimator, we make use of the probability distribution of the point estimator.

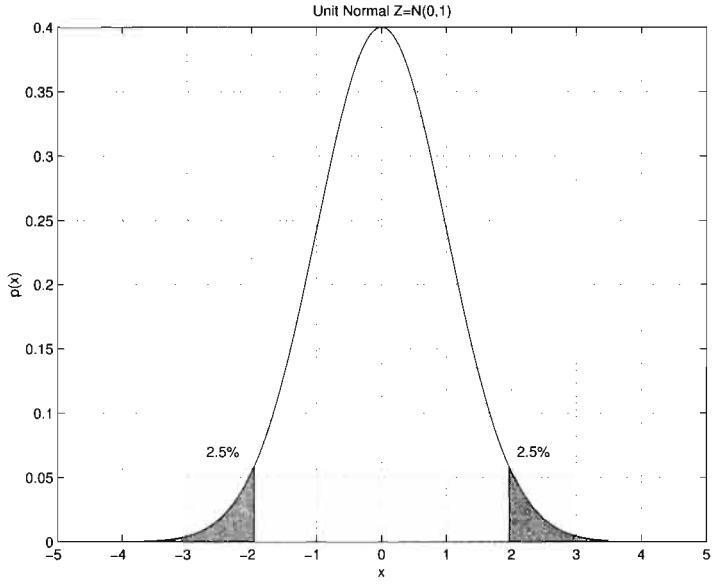

Figure 14.2 95 percent of the unit normal distribution lies between −1.96 and 1.96.

For example, let us say we are trying to estimate the mean μ of a normal density from a sample $\mathcal{X} = \{x^t\}_{t=1}^N$. $m = \sum_t x^t/N$ is the sample average and is the point estimator to the mean. m is the sum of normals and therefore is also normal, $m \sim \mathcal{N}(\mu, \sigma^2/N)$. We define the statistic with a *unit normal distribution:*

UNIT NORMAL DISTRIBUTION

$$\sqrt{N}\frac{(m-\mu)}{\sigma} \sim \mathcal{Z} \tag{14.2}$$

We know that 95 percent of $\mathcal{Z}$ lies in $(-1.96, 1.96)$, namely, $P\{-1.96 < \mathcal{Z} < 1.96\} = 0.95$, and we can write (see figure 14.2)

$$P\left\{-1.96 < \sqrt{N}\frac{(m-\mu)}{\sigma} < 1.96\right\} = 0.95$$

or equivalently

$$P\left\{m - 1.96\frac{\sigma}{\sqrt{N}} < \mu < m + 1.96\frac{\sigma}{\sqrt{N}}\right\} = 0.95$$

That is "with 95 percent confidence," μ will lie within $1.96\sigma/\sqrt{N}$ units of the sample average. This is a *two-sided confidence interval.* With 99

TWO-SIDED CONFIDENCE INTERVAL

percent confidence, μ will lie in $(m - 2.58\sigma/\sqrt{N}, m + 2.58\sigma/\sqrt{N})$, that is if we want more confidence, the interval gets larger. The interval gets smaller as N, the sample size, increases.

This can be generalized for any required confidence as follows: Let us denote z_α such that

$$P\{Z > z_\alpha\} = \alpha, \ 0 < \alpha < 1$$

Because Z is symmetric around the mean, $z_{1-\alpha/2} = -z_{\alpha/2}$, and $P\{X < -z_{\alpha/2}\} = P\{X > z_{\alpha/2}\} = \alpha/2$. Hence for any specified level of confidence $1 - \alpha$, we have

$$P\{-z_{\alpha/2} < Z < z_{\alpha/2}\} = 1 - \alpha$$

and

$$P\left\{-z_{\alpha/2} < \sqrt{N}\frac{(m-\mu)}{\sigma} < z_{\alpha/2}\right\} = 1 - \alpha$$

or

$$P\left\{m - z_{\alpha/2}\frac{\sigma}{\sqrt{N}} < \mu < m + z_{\alpha/2}\frac{\sigma}{\sqrt{N}}\right\} = 1 - \alpha \quad (14.3)$$

Hence a $100(1 - \alpha)$ percent two-sided confidence interval for μ can be computed for any α.

Similarly, knowing that $P\{Z < 1.64\} = 0.95$, we have (see figure 14.3)

$$P\left\{\sqrt{N}\frac{(m-\mu)}{\sigma} < 1.64\right\} = 0.95$$

or

$$P\left\{m - 1.64\frac{\sigma}{\sqrt{N}} < \mu\right\} = 0.95$$

ONE-SIDED CONFIDENCE INTERVAL

and $(m - 1.64\sigma/\sqrt{N}, \infty)$ is a 95 percent *one-sided upper confidence interval* for μ, which defines a lower bound. Generalizing, a $100(1 - \alpha)$ percent one-sided confidence interval for μ can be computed from

$$P\left\{m - z_\alpha\frac{\sigma}{\sqrt{N}} < \mu\right\} = 1 - \alpha \quad (14.4)$$

Similarly, the one-sided lower confidence interval that defines an upper bound can also be calculated.

In the previous intervals, we used σ; that is, we assumed that the variance is known. If it is not, one can plug the sample variance

$$S^2 = \sum_t (x^t - m)^2/(N - 1)$$

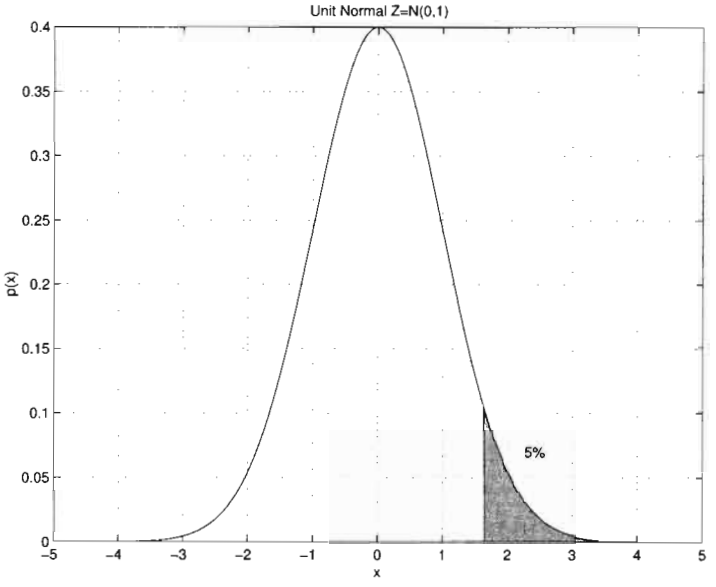

Figure 14.3 95 percent of the unit normal distribution lies before 1.64.

instead of σ^2. We know that when $x^t \sim \mathcal{N}(\mu, \sigma^2)$, $(N-1)S^2/\sigma^2$ is chi-square with $N-1$ degrees of freedom. We also know that m and S^2 are independent. Then, $\sqrt{N}(m-\mu)/S$ is t distributed with $N-1$ degrees of freedom (section A.3.7), denoted as

$$\frac{\sqrt{N}(m-\mu)}{S} \sim t_{N-1} \tag{14.5}$$

t DISTRIBUTION

Hence for any $\alpha \in (0, 1/2)$, we can define an interval, using the values specified by the *t distribution,* instead of the unit normal Z

$$P\left\{t_{1-\alpha/2,N-1} < \sqrt{N}\frac{(m-\mu)}{S} < t_{\alpha/2,N-1}\right\} = 1-\alpha$$

or using that $t_{1-\alpha/2,N-1} = -t_{\alpha/2,N-1}$

$$P\left\{m - t_{\alpha/2,N-1}\frac{S}{\sqrt{N}} < \mu < m + t_{\alpha/2,N-1}\frac{S}{\sqrt{N}}\right\} = 1-\alpha$$

Similarly, one-sided confidence intervals can be defined. The t distribution has larger spread (longer tails) than the unit normal distribution, and generally the interval given by the t is larger; this should be expected since additional uncertainty exists due to the unknown variance.

14.5 Hypothesis Testing

Instead of explicitly estimating some parameters, in certain applications we may want to use the sample to test some particular hypothesis concerning the parameters. For example, instead of estimating the mean, we may want to test whether the mean is less than 0.02. If the random sample is consistent with the hypothesis under consideration, we say that the hypothesis is "accepted"; otherwise, we say that it is "rejected." But when we make such a decision, we are not really saying that it is true but rather that the sample data appears to be consistent with it to a given degree of confidence.

HYPOTHESIS TESTING

In *hypothesis testing,* the approach is as follows: We define a statistic that obeys a certain distribution if the hypothesis is correct. If the statistic calculated from the sample has a high enough probability of being drawn from this distribution, then we accept the hypothesis; otherwise, we reject it.

Let us say we have a sample from a normal distribution with unknown mean μ and known variance σ^2, and we want to test a specific hypothesis about μ, for example, whether it is equal to a specified constant μ_0. It is denoted as H_0 and is called the *null hypothesis*

NULL HYPOTHESIS

$$H_0 : \mu = \mu_0$$

against the alternative hypothesis

$$H_1 : \mu \neq \mu_0$$

m is the point estimate of μ, and it is reasonable to accept H_0 if m is not too far from μ_0. This is where the interval estimate is used: We accept the hypothesis with *level of significance* α if μ_0 lies in the $100(1-\alpha)$ percent confidence interval, namely, H_0 is accepted if

LEVEL OF SIGNIFICANCE

$$\frac{\sqrt{N}(m-\mu_0)}{\sigma} \in (-z_{\alpha/2}, z_{\alpha/2}) \tag{14.6}$$

This is a *two-sided test.* If we reject when the hypothesis is correct, this is a *type I error* and thus α, set before the test, defines how much type I error we can tolerate, typical values being $\alpha = 0.1, 0.05, 0.01$ (see table 14.2). A *type II error* is if we accept the null hypothesis when the true mean μ is unequal to μ_0. The probability that H_0 is accepted when the true mean is μ is a function of μ and is given as

TWO-SIDED TEST

TYPE I ERROR

TYPE II ERROR

$$\beta(\mu) = P_\mu \left\{ -z_{\alpha/2} \leq \frac{m-\mu_0}{\sigma/\sqrt{N}} \leq z_{\alpha/2} \right\} \tag{14.7}$$

Table 14.2 Type I error, type II error, and power of a test.

	Decision	
Truth	Accept	Reject
True	Correct	Type I error
False	Type II error	Correct (Power)

POWER FUNCTION

$1 - \beta(\mu)$ is called the *power function* of the test and is equal to the probability of rejection when μ is the true value.

ONE-SIDED TEST

One can also have a *one-sided test* of the form

$$H_0 : \mu \leq \mu_0$$
$$H_1 : \mu > \mu_0$$

as opposed to the two-sided test when the alternative hypothesis is $\mu \neq \mu_0$. The α level of significance one-sided test defines the $100(1 - \alpha)$ confidence interval bounded on one side in which m should lie for the hypothesis to be accepted. We accept if

$$\frac{\sqrt{N}}{\sigma}(m - \mu_0) \in (-\infty, z_\alpha) \tag{14.8}$$

If the variance is unknown, just as we did in the interval estimates, we use the sample variance instead of the population variance and the fact that

$$\frac{\sqrt{N}(m - \mu_0)}{S} \sim t_{N-1} \tag{14.9}$$

For example, for $H_0 : \mu = \mu_0$ versus $H_1 : \mu \neq \mu_0$, we accept at significance level α if

$$\frac{\sqrt{N}(m - \mu_0)}{S} \in (-t_{\alpha/2,N-1}, t_{\alpha/2,N-1}) \tag{14.10}$$

t TEST

This is known as the *two-sided t test.* A one-sided t test can be defined similarly.

14.6 Assessing a Classification Algorithm's Performance

Now that we have reviewed hypothesis testing, we are ready to see how it is used in testing error rates. We start with error rate assessment and in the next section, we discuss error rate comparison.

14.6.1 Binomial Test

Let us start with the case where we have a single training set $\mathcal{T}$ and a single validation set $\mathcal{V}$. We train our classifier on $\mathcal{T}$ and test it on $\mathcal{V}$. We denote by p the probability that the classifier makes a misclassification error. We do not know p; it is what we would like to estimate or test a hypothesis about. On the instance with index t from the validation set $\mathcal{V}$, let us say x^t denotes the correctness of the classifier's decision. Then x^t is 0/1; x^t is Bernoulli distributed where with probability p, it commits an error and x^t takes the value 1 and with probability $1 - p$, it is successful and x^t is 0. The point estimate is (section 4.2.1)

$$\hat{p} = \frac{\sum_t x^t}{N} \tag{14.11}$$

where $N = |\mathcal{V}|$. But now we would like to test whether the error probability p is less than or equal to some value p_0 we specify. The question can be phrased as follows: Given that the classifier makes e errors on a validation set of size N, can we say that the classifier has error probability p_0 or less?

We have the hypothesis test

$$H_0 : p \leq p_0 \text{ vs. } H_1 : p > p_0$$

Let X denote the number of errors on a validation set of size N:

$$X = \sum_{t=1}^{N} x^t$$

Because x^t are independent Bernoulli distributed random variables, their sum X is binomial. If the probability of error is p, the probability that the classifier commits j errors out of N is

$$P\{X = j\} = \binom{N}{j} p^j (1-p)^{N-j}$$

Under the null hypothesis, we assume that p is (at most) p_0, and the probability that there are e errors is

$$P\{X \leq e\} = \sum_{j=1}^{e} \binom{N}{j} {p_0}^j (1-p_0)^{N-j} \tag{14.12}$$

BINOMIAL TEST

If this probability is less than the allowed probability $1 - \alpha$, the *binomial test* accepts the hypothesis; otherwise, we reject it.

14.6.2 Approximate Normal Test

The binomial test is costly to compute. Because X is the sum of independent random variables from the same distribution, the central limit theorem states that for large N and small p_0, X is approximately normally distributed with mean Np_0 and variance $Np_0(1 - p_0)$. Then

$$\frac{X - Np_0}{\sqrt{Np_0(1 - p_0)}} \doteq Z \tag{14.13}$$

APPROXIMATE NORMAL TEST

where $\doteq$ denotes "approximately distributed." Then the *approximate normal test* accepts the null hypothesis if this value for $X = e$ is less than or equal to $z_{1-\alpha}$. $z_{0.95}$ is 1.64. This test may give erroneous results for $Np_0 > 20$.

14.6.3 Paired t Test

The two tests we discussed earlier use a single validation set. If we run the algorithm K times, on K training/validation set pairs, we get K error percentages, $p_i, i = 1, \ldots, K$ on the K validation sets. Let x_i^t be 1 if the classifier trained on $\mathcal{T}_i$ makes a misclassification error on instance t of $\mathcal{V}_i$; x_i^t is 0 otherwise. Then

$$p_i = \frac{\sum_{t=1}^{N} x_i^t}{N}$$

Given that

$$m = \frac{\sum_{i=1}^{K} p_i}{K}, \quad S^2 = \frac{\sum_{i=1}^{K} (p_i - m)^2}{K - 1}$$

from equation 14.9, we know that we have

$$\frac{\sqrt{K}(m - p_0)}{S} \sim t_{K-1} \tag{14.14}$$

PAIRED t TEST

and the *paired t test* accepts the null hypothesis that the classification algorithm has p_0 or less error percentage at significance level α if this value is less than or equal to $t_{\alpha,K-1}$. Typically K is taken as 10 or 30. $t_{0.05,9} = 1.83$ and $t_{0.05,29} = 1.70$.

14.7 Comparing Two Classification Algorithms

Given two learning algorithms and a training set, we want to compare and test whether the two algorithms construct classifiers that have the same expected error rate on a new example.

14.7.1 McNemar's Test

CONTINGENCY TABLE

Given a training set and a validation set, we use two algorithms to train two classifiers on the training set and test them on the validation set and compute their errors. A *contingency table,* like the one shown here, is an array of natural numbers in matrix form representing counts, or frequencies:

e_{00}: Number of examples misclassified by both	e_{01}: Number of examples misclassified by 1 but not 2
e_{10}: Number of examples misclassified by 2 but not 1	e_{11}: Number of examples correctly classified by both

Under the null hypothesis that the classification algorithms have the same error rate, we expect $e_{01} = e_{10}$ and these to be equal to $(e_{01}+e_{10})/2$. We have the chi-square statistic with one degree of freedom

$$\frac{(|e_{01} - e_{10}| - 1)^2}{e_{01} + e_{10}} \sim \chi_1^2 \tag{14.15}$$

MCNEMAR'S TEST

and *McNemar's test* accepts the hypothesis that the two classification algorithms have the same error rate at significance level α if this value is less than or equal to $\chi^2_{\alpha,1}$. $\chi^2_{0.05,1} = 3.84$.

14.7.2 *K*-Fold Cross-Validated Paired *t* Test

This set uses K-fold cross-validation to get K training/validation set pairs. We use the two classification algorithms to train on the training sets $\mathcal{T}_i, i = 1,\ldots,K$, and test on the validation sets $\mathcal{V}_i$. The error percentages of the classifiers on the validation sets are recorded as p_i^1 and p_i^2. If the two classification algorithms have the same error rate, then we expect them to have the same mean, or equivalently, that the difference of their means is 0.

The difference in error rates on fold i is $p_i = p_i^1 - p_i^2$. When this is done K times, we have a distribution of p_i containing K points. Given that p_i^1 and p_i^2 are both (approximately) normal, their difference p_i is also normal. The null hypothesis is that this distribution has 0 mean:

$$H_0 : \mu = 0$$
$$H_1 : \mu \neq 0$$

We define

$$m = \frac{\sum_{i=1}^K p_i}{K}, \quad S^2 = \frac{\sum_{i=1}^K (p_i - m)^2}{K - 1}$$

Under the null hypothesis that $\mu = 0$, we have a statistic that is t distributed with $K - 1$ degrees of freedom:

$$\frac{\sqrt{K}(m-0)}{S} = \frac{\sqrt{K} \cdot m}{S} \sim t_{K-1} \tag{14.16}$$

K-FOLD CV PAIRED t TEST

Thus the *K-fold cv paired t test* accepts the hypothesis that two classification algorithms have the same error rate at significance level α if this value is in the interval $(-t_{\alpha/2,K-1}, t_{\alpha/2,K-1})$. $t_{0.025,9} = 2.26$ and $t_{0.025,29} = 2.05$.

14.7.3 5 × 2 cv Paired t Test

In the 5×2 cv t test, proposed by Dietterich (1998), we perform five replications of twofold cross-validation. In each replication, the dataset is divided into two equal-sized sets. $p_i^{(j)}$ is the difference between the error rates of the two classifiers on fold $j = 1, 2$ of replication $i = 1, \ldots, 5$. The average on replication i is $\overline{p}_i = (p_i^{(1)} + p_i^{(2)})/2$, and the estimated variance is $s_i^2 = (p_i^{(1)} - \overline{p}_i)^2 + (p_i^{(2)} - \overline{p}_i)^2$.

Under the null hypothesis that the two classification algorithms have the same error rate, $p_i^{(j)}$ is the difference of two identically distributed proportions, and ignoring the fact that these proportions are not independent, $p_i^{(j)}$ can be treated as approximately normal distributed with 0 mean and unknown variance σ^2. Then $p_i^{(j)}/\sigma$ is approximately unit normal. If we assume $p_i^{(1)}$ and $p_i^{(2)}$ are independent normals (which is not strictly true because their training and test sets are not drawn independently of each other), then s_i^2/σ^2 has a chi-square distribution with one degree of freedom. If each of the s_i^2 are assumed to be independent (which is not true because they are all computed from the same set of available data), then their sum is chi-square with five degrees of freedom:

$$M = \frac{\sum_{i=1}^{5} s_i^2}{\sigma^2} \sim \chi_5^2$$

and

$$t = \frac{p_1^{(1)}}{\sqrt{M/5}} = \frac{p_1^{(1)}}{\sqrt{\sum_{i=1}^{5} s_i^2/5}} \sim t_5 \tag{14.17}$$

5 × 2 CV PAIRED t TEST

giving us a t statistic with five degrees of freedom. The 5×2 *cv paired t test* accepts the hypothesis that the two classification algorithms have

the same error rate at significance level α if this value is in the interval $(-t_{\alpha/2,5}, t_{\alpha/2,5})$. $t_{0.025,5} = 2.57$.

We can also define a one-sided version of this test to check if the expected error rate of the first classification algorithm is less than or equal to that of the second one, namely:

$$H_0 : \mu \leq 0$$
$$H_1 : \mu > 0$$

We calculate the same statistic as in equation 14.17 and accept the null hypothesis if it is less than $t_{\alpha,5}$. $t_{0.05,5} = 2.02$.

14.7.4 5 × 2 cv Paired *F* Test

We note that the numerator in equation 14.17, $p_1^{(1)}$, is arbitrary; actually, ten different values can be placed in the numerator, namely, $p_i^{(j)}, j = 1, 2, i = 1, \ldots, 5$, leading to ten possible statistics:

$$t_i^{(j)} = \frac{p_i^{(j)}}{\sqrt{\sum_{i=1}^{5} s_i^2/5}} \tag{14.18}$$

Alpaydın (1999) proposed an extension to the 5 × 2 cv t test that combines the results of the ten possible statistics. If $p_i^{(j)}/\sigma \sim \mathcal{Z}$, then $\left(p_i^{(j)}\right)^2/\sigma^2 \sim \chi_1^2$ and their sum is chi-square with ten degrees of freedom:

$$N = \frac{\sum_{i=1}^{5}\sum_{j=1}^{2}\left(p_i^{(j)}\right)^2}{\sigma^2} \sim \chi_{10}^2$$

Placing this in the numerator of equation 14.17, we get a statistic that is the ratio of two chi-square distributed random variables. Two such variables divided by their respective degrees of freedom is F distributed with ten and five degrees of freedom (section A.3.8):

$$f = \frac{N/10}{M/5} = \frac{\sum_{i=1}^{5}\sum_{j=1}^{2}\left(p_i^{(j)}\right)^2}{2\sum_{i=1}^{5} s_i^2} \sim F_{10,5} \tag{14.19}$$

5 × 2 CV PAIRED *F* TEST

5 × 2 cv paired F test accepts the hypothesis that the classification algorithms have the same error rate at significance level α if this value is less than $F_{\alpha,10,5}$. $F_{0.05,10,5} = 4.74$.

14.8 Comparing Multiple Classification Algorithms: Analysis of Variance

In many cases, we have more than two candidate classification algorithms, and we would like to find the most accurate. Given L candidate classification algorithms, we train them on K training sets, induce K classifiers with each algorithm, and then test them on K validation sets and record their error rates. This gives us L groups of K values. The problem then is the comparison of these L samples for statistically significant difference.

ANALYSIS OF VARIANCE

In *analysis of variance* (anova), we consider L independent samples, each of size K, composed of normal random variables of unknown mean μ_j and unknown common variance σ^2:

$$X_{ij} \sim \mathcal{N}(\mu_j, \sigma^2), j = 1, \ldots, L, \; i = 1, \ldots, K,$$

and we are interested in testing the hypothesis H_0 that all means are equal:

$$H_0 : \mu_1 = \mu_2 = \cdots = \mu_L$$

The comparison of error rates of multiple classification algorithms fits this scheme. We have L classification algorithms, and we have their error rates on K validation folds. X_{ij} is the number of validation errors made by the classifier, which is trained by classification algorithm j on fold i. Each X_{ij} is binomial and approximately normal. If H_0 is accepted, we conclude that there is no significant error difference among the error rates of the L classification algorithms. This is therefore a generalization of the tests we saw in section 14.7 that compared the error rates of two classification algorithms. The L classification algorithms may be different or use different hyperparameters, for example, number of hidden units in a multilayer perceptron, number of neighbors in k-nn, and so forth.

The approach in anova is to derive two estimators of σ^2. One estimator is designed such that it is true only when H_0 is true, and the second is always a valid estimator, regardless of whether H_0 is true or not. Anova then rejects H_0, namely, that the L samples are drawn from the same population, if the two estimators differ significantly.

Our first estimator to σ^2 is valid only if the hypothesis is true, namely, $\mu_j = \mu, j = 1, \ldots, L$. If $X_{ij} \sim \mathcal{N}(\mu, \sigma^2)$, then the group average

$$m_j = \sum_{i=1}^{K} \frac{X_{ij}}{K}$$

is also normal with mean μ and variance σ^2/K. If the hypothesis is true, then $m_j, j = 1, \ldots, L$ are L instances drawn from $\mathcal{N}(\mu, \sigma^2/K)$. Then *their* mean and variance are

$$m = \frac{\sum_{j=1}^{L} m_j}{L}, \quad S^2 = \frac{\sum_j (m_j - m)^2}{L - 1}$$

Thus an estimator of σ^2 is $K \cdot S^2$, namely,

$$\hat{\sigma}^2 = K \sum_{j=1}^{L} \frac{(m_j - m)^2}{L - 1} \tag{14.20}$$

Each of m_j is normal and $(L-1)S^2/(\sigma^2/K)$ is chi-square with $(L-1)$ degrees of freedom. Then, we have

$$\sum_j \frac{(m_j - m)^2}{\sigma^2/K} \sim \chi^2_{L-1} \tag{14.21}$$

We define SS_b, the between-group sum of squares, as

$$SS_b \equiv K \sum_j (m_j - m)^2$$

So, when H_0 is true, we have

$$\frac{SS_b}{\sigma^2} \sim \chi^2_{L-1} \tag{14.22}$$

Our second estimator of σ^2 is the average of group variances, S_j^2, defined as

$$S_j^2 = \frac{\sum_{i=1}^{K} (X_{ij} - m_j)^2}{K - 1}$$

and their average is

$$\hat{\sigma}^2 = \sum_{j=1}^{L} \frac{S_j^2}{L} = \sum_j \sum_i \frac{(X_{ij} - m_j)^2}{L(K-1)} \tag{14.23}$$

We define SS_w, the within-group sum of squares:

$$SS_w \equiv \sum_j \sum_i (X_{ij} - m_j)^2$$

Remembering that for a normal sample, we have

$$(K-1)\frac{S_j^2}{\sigma^2} \sim \chi^2_{K-1}$$

and that the sum of chi-squares is also a chi-square, we have

$$(K-1)\sum_{j=1}^{L}\frac{S_j^2}{\sigma^2} \sim \chi^2_{L(K-1)}$$

So

$$\frac{SS_w}{\sigma^2} \sim \chi^2_{L(K-1)} \tag{14.24}$$

We should reject H_0 if the two estimators disagree significantly. If H_0 is not true, then the first estimator will overestimate σ^2. The ratio of two independent chi-square random variables divided by their respective degrees of freedom is a random variable that is F distributed, and hence when H_0 is true, we have

$$\left(\frac{SS_b/\sigma^2}{L-1}\right) \Big/ \left(\frac{SS_w/\sigma^2}{L(K-1)}\right) = \frac{SS_b/(L-1)}{SS_w/(L(K-1))} \sim F_{L-1,L(K-1)} \tag{14.25}$$

For any given significance value α, the hypothesis that the L classification algorithms have the same expected error rate is accepted if this statistic is less than $F_{\alpha,L-1,L(K-1)}$. This is the basic *one-way* analysis of variance where there is a single factor, for example, classification algorithm.

If the hypothesis is rejected, we only know that there is some difference between the L groups; we do not know how the error rates of the classification algorithms differ. We can then do anova on subsets of classification algorithms to determine the subsets with comparable error rates. We do not need to consider all possible subsets; we order classification algorithms in terms of average error and then test only consecutive ones. To find the largest groups, we go from larger to smaller subsets: First we test all L; if this rejects, there are two subsets of $L-1$ (leaving out the two at either end), and so on. At the end, we have groups in which there is no significant difference. For example, we can have the result 145 23, which implies that we have two groups, one formed of classification methods 1, 4, 5, and the other formed of 2 and 3.

There are also nonparametric tests to allow checking for *contrasts* (Dean and Voss 1999): Let us say 1 and 2 are parametric methods and 3 and 4 are nonparametric methods. We can then test whether the average of 1 and 2 differs from the average of 3 and 4.

Or, we can use a series of pairwise comparisons using the tests we discussed in section 14.7 to check for pairwise differences. In statistics, this

MULTIPLE COMPARISONS

is called *multiple comparisons.* There is, however, one point we need to pay attention to if we decide after applying a set of tests: If m hypotheses are to be tested, each at significance level α, then the probability that at least one hypothesis is incorrectly rejected is at most $m\alpha$. For example, the probability that six confidence intervals, each calculated at 95 percent individual confidence intervals, will simultaneously be correct is at least 70 percent. Thus to ensure that the overall confidence interval is at least $100(1 - \alpha)$, each confidence interval should be set at $100(1 - \alpha/m)$. This is called a *Bonferroni correction.*

BONFERRONI CORRECTION

Note that the main cost is the training and testing of L classification algorithms on K training/validation sets. Once this is done and the values are stored in a $K \times L$ table, calculating the anova or pairwise comparison test statistics from those is very cheap in comparison.

14.9 Notes

A more detailed discussion of interval estimation, hypothesis testing, and analysis of variance can be found in any introductory statistics book, for example, Ross 1987. Dietterich (1998) discusses statistical tests and compares them on a number of applications using different classification algorithms. Jensen and Cohen (2000) discuss how the hyperparameters of a learner can be optimized.

In comparing two classification algorithms, note that we are testing only whether they have the same expected error rate. If they do, this does not mean that they make the same errors. This is an idea that we will discuss in chapter 15; we can combine multiple models to improve accuracy if different classifiers make different errors.

Another important point to note is that we are only assessing or comparing misclassifications. This implies that from our point of view, all misclassifications have the same cost. When this is not the case, our tests should be based on risks taking a suitable loss function into account (section 3.3). Not much work has been done in this area. Similarly, these tests should be generalized from classification to regression, so as to be able to assess the mean square errors of regression algorithms (section 4.6), or to be able to compare the errors of two regression algorithms.

The tests we discussed are parametric in that we assumed certain parametric models and defined hypotheses on the parameters, for example, $H_0 : \mu = 0$. There are also *nonparametric tests* (Conovar 1999). For exam-

NONPARAMETRIC TEST

ple, the Kruskal-Wallis test is the nonparametric version of anova where we are given a number of samples, each from one population, and we want to test the null hypothesis that all of the populations are identical. The Newman-Keuls test is a nonparametric range test that finds subsets with comparable error rates and then orders these subsets; for example, it can find orderings such as 145 23. Methods of multiple comparisons are discussed in Dean and Voss 1999.

STATLOG

The *Statlog* project (Michie, Spiegelhalter, and Taylor 1994) compared twenty different classification algorithms on a large number of applications. Another is the *Delve* project that allows researchers to add new datasets and classification algorithms and compare with others (Hinton and Delve Team Members 1995).

DELVE

When we compare two or more algorithms, if the null hypothesis that they have the same error rate is accepted, we choose the simpler one, namely, the one with less space or time complexity. That is, we use our prior preference if the data does not prefer one of the learning algorithms in terms of error rate. For example, if we compare a linear model and a nonlinear model and if the test accepts that they have the same expected error rate, we should go for the simpler linear model. Even if the test rejects, in choosing one algorithm over another, error rate is only one of the criteria. Other criteria like training (space/time) complexity, testing complexity, and interpretability may override in practical applications.

14.10 Exercises

1. We can simulate a classifier with error probability p by drawing samples from a Bernoulli distribution. Doing this, implement the binomial, approximate, and t tests for $p_0 \in (0, 1)$. Repeat these tests at least 1,000 times for several values of p and calculate the probability of rejecting the null hypothesis. What do you expect the probability of reject to be when $p_0 = p$?
2. Assume $x^t \sim \mathcal{N}(\mu, \sigma^2)$ where σ^2 is known. How can we test for $H_0 : \mu \geq \mu_0$ vs. $H_1 : \mu < \mu_0$?
3. The K-fold cross-validated t test only tests for the equality of error rates. If the test rejects, we do not know which classification algorithm has the lower error rate. How can we test whether the first classification algorithm does not have higher error rate than the second one? Hint: We have to test $H_0 : \mu \leq 0$ vs. $H_1 : \mu > 0$.
4. Let us say we have three classification algorithms. How can we order these three from best to worst?

15 *Combining Multiple Learners*

We discussed many different learning algorithms in the previous chapters. Though these are generally successful, no one single algorithm is always the most accurate. Now, we are going to discuss models composed of multiple learners that complement each other so that by combining them, we attain higher accuracy.

15.1 Rationale

IN ANY APPLICATION, we can use one of several learning algorithms, and with certain algorithms, there are hyperparameters that affect the final learner. For example, in a classification setting, we can use a parametric classifier or a multilayer perceptron, and for example, with a multilayer perceptron, we should also decide on the number of hidden units. The No Free Lunch Theorem states that there is no single learning algorithm that in any domain always induces the most accurate learner. The usual approach is to try many and choose the one that performs the best on a separate validation set, as we discussed in chapter 14.

Each learning algorithm dictates a certain model that comes with a set of assumptions. This inductive bias leads to error if the assumptions do not hold for the data. Learning is an ill-posed problem and with finite data, each algorithm converges to a different solution and fails under different circumstances. The performance of a learner may be fine-tuned to get the highest possible accuracy on a validation set, but this fine-tuning is a complex task and still there are instances on which even the best learner is not accurate enough. The idea is that there may be another learner that is accurate on these. By suitably combining multiple learners then, accuracy can be improved. Recently with computation and mem-

ory getting cheaper, such systems composed of multiple learners have become popular.

BASE-LEARNERS

Since there is no point in combining learners that always make similar decisions, the aim is to be able to find a set of *base-learners* who differ in their decisions so that they will complement each other. There are different "knobs" that we can play with to achieve this:

1. The easiest is to use *different learning algorithms* to train the different base-learners. Different algorithms make different assumptions about the data and lead to different classifiers. For example, one base-learner may be parametric and another may be nonparametric. When we decide on a single algorithm, we give emphasis to a single method and ignore all others. Combining multiple learners based on multiple algorithms, we free ourselves from taking a decision and we no longer put all our eggs in one basket.

2. We can use the same learning algorithm but use it with *different hyperparameters*. Examples are the number of hidden units in a multilayer perceptron, k in k-nearest neighbor, error threshold in decision trees, and so forth. With a Gaussian parametric classifier, whether the covariance matrices are shared or not, is a hyperparameter. If the optimization algorithm uses an iterative procedure such as gradient descent whose final state depends on the initial state, such as in backpropagation with multilayer perceptrons, the initial state, for example, the initial weights, is another hyperparameter. When we train multiple base-learners with different hyperparameter values, we average over it and reduce variance, and therefore error.

3. Separate base-learners may also be using *different representations* of the same input object or event, making it possible to integrate different types of sensors/measurements or features. Different representations make different characteristics explicit allowing better identification. In many applications, there are multiple sources of information, and it is desirable to use all of these data to extract more information and achieve higher accuracy in prediction. For example, in speech recognition, to recognize the uttered words, additional to the acoustic input, we can also use the video image of the speaker's lips as the words are spoken. This is similar to *sensor fusion* where the data from different sensors are integrated to extract more information for a specific application. The simplest approach is to concatenate all data vec-

SENSOR FUSION

tors and treat it as one large vector from a single source, but this does not seem theoretically appropriate since this corresponds to modeling data as sampled from one multivariate statistical distribution. Moreover, larger input dimensionalities make the systems more complex and require larger samples for the estimators to be accurate. The approach we take is to make separate predictions based on different sources using separate base-learners, then combine their predictions.

4. Another possibility is to have *different training sets* to train the different base-learners. This can be done randomly by drawing random training sets from the given sample; this is called *bagging.* Or, the learners can be trained serially so that instances on which the preceding base-learners are not accurate are given more emphasis in training later base-learners; examples are *boosting* and *cascading,* which actively try to generate complementary learners, instead of leaving this to chance. The partitioning of the training sample can also be done based on locality in the input space so that each base-learner is trained on instances in a certain local part of the input space; this is what is done by the *mixture of experts* that we discussed in chapter 12 but that we revisit in this context of combining multiple learners. Similarly, it is possible to define the main task in terms of a number of subtasks to be implemented by the base-learners, as is done by *error-correcting output codes.*

One important note is that when we generate multiple base-learners, we want them to be reasonably accurate but do not require them to be very accurate individually, so they are not, and need not be, optimized separately for best accuracy. The base-learners are not chosen for their accuracy, but for their simplicity. We do require, however, that the base-learners be accurate on different instances, specializing in subdomains of the problem. What we care for is the final accuracy when the base-learners are combined, rather than the accuracies of the base-learners we started from. Let us say we have a classifier that is 80 percent accurate. When we decide on a second classifier, we do not care for the overall accuracy; we only care about how accurate it is on the 20 percent that the first classifier misclassifies, as long as we know when to use which one.

In addition to how the learners are trained, there are also different ways the multiple base-learners are combined to generate the final output:

MULTIEXPERT COMBINATION

- *Multiexpert combination* methods have base-learners that work in *par-*

allel. All of them are trained and then given an instance, they all give their decisions, and a separate combiner computes the final decision using their predictions. Examples include *voting* and its variants, *mixture of experts,* and *stacked generalization.*

MULTISTAGE COMBINATION

- *Multistage combination* methods use a *serial* approach where the next base-learner is trained with or tested on only the instances where the previous base-learners are not accurate enough. The idea is that the base-learners (or the different representations they use) are sorted in increasing complexity so that a complex base-learner is not used (or its complex representation is not extracted) unless the preceding simpler base-learners are not confident. An example is *cascading.*

Let us say that we have L base-learners. We denote by $d_j(x)$ the prediction of base-learner $\mathcal{M}_j$ given the arbitrary dimensional input x. In the case of multiple representations, each $\mathcal{M}_j$ uses a different input representation x_j. The final prediction is calculated from the predictions of the base-learners:

$$y = f(d_1, d_2, \ldots, d_L|\Phi) \tag{15.1}$$

where $f(\cdot)$ is the combining function with Φ denoting its parameters. When there are K outputs, each learner has K outputs, $d_{ji}(x), i = 1, \ldots, K$, $j = 1, \ldots, L$, and combining them, we also generate K values, $y_i, i = 1, \ldots, K$ and then for example in classification, we choose the class with the maximum y_i value.

15.2 Voting

VOTING

The simplest way to combine multiple classifiers is by *voting,* which corresponds to taking a linear combination of the learners. This is also known as *ensembles* and *linear opinion pools.* Let us denote by w_j the weight of learner j. Then the final output is computed as (see figure 15.1)

ENSEMBLES
LINEAR OPINION POOLS

$$y = \sum_{j=1}^{L} w_j d_j \tag{15.2}$$

satisfying

$$w_j \geq 0, \forall j \text{ and } \sum_{j=1}^{L} w_j = 1$$

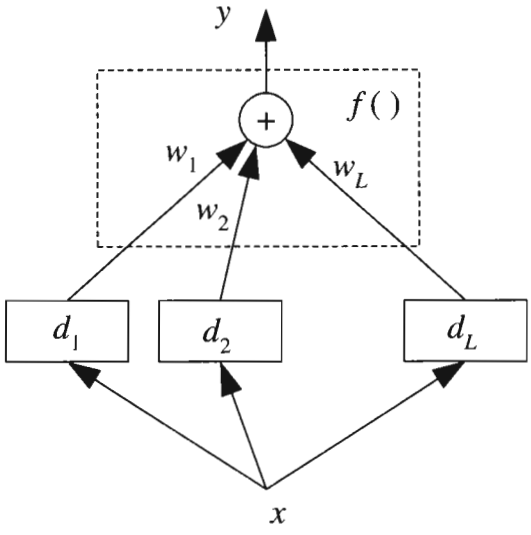

Figure 15.1 In voting, the combiner function $f(\cdot)$ is a weighted sum. d_j are the multiple learners, and w_j are the weights of their votes. y is the overall output. In the case of multiple outputs, for example, classification, the learners have multiple outputs d_{ji} whose weighted sum gives y_i. Note also that in the diagram, all learners observe the same input; it may be the case that different learners observe different representations of the same input object or event.

Here, $f(\cdot)$ of equation 15.1 corresponds to a weighted sum where Φ is the set of weights, $w_1, \ldots, w_L$.

In regression, we take the weighted average of the individual predictions. The name voting comes from its use in classification

$$y_i = \sum_{j=1}^{L} w_j d_{ji} \tag{15.3}$$

where d_{ji} is the vote of learner j for class C_i and w_j is the weight of its vote. In the simplest case, we have *simple voting* where all voters have equal weight, namely, $w_j = 1/L$. In classification, this is called *plurality voting* where the class having the maximum number of votes is the winner. When there are two classes, this is *majority voting* where the winner class gets more than half of the votes (exercise 1). If the voters can also supply the additional information of how much they vote for each class

(e.g., by the posterior probability), then after normalization, these can be used as weights in a *weighted voting* scheme. Equivalently, if d_{ji} are the class posterior probabilities, $P(C_i|x, \mathcal{M}_j)$, then we can just sum them up ($w_j = 1/L$) and choose the class with maximum y_i.

Another possibility is to assess the accuracies of the learners (regressor or classifier) on a separate validation set and use that information to compute the weights, so that we give more weights to more accurate learners.

BAYESIAN MODEL COMBINATION

Voting schemes can be seen as approximations under a Bayesian framework with weights approximating prior model probabilities, and model decisions approximating model-conditional likelihoods. This is *Bayesian model combination.* For example, in classification we have $w_j \equiv P(\mathcal{M}_j)$, $d_{ji} = P(C_i|x, \mathcal{M}_j)$, and equation 15.3 corresponds to

$$P(C_i|x) = \sum_{\text{all models } \mathcal{M}_j} P(C_i|x, \mathcal{M}_j)P(\mathcal{M}_j) \tag{15.4}$$

Simple voting corresponds to a uniform prior. If we have a prior distribution preferring simpler models, this would give larger weights to them. We cannot integrate over all models; we only choose a subset for which we believe $P(\mathcal{M}_j)$ is high, or we can have another Bayesian step and calculate $P(\mathcal{M}_j|\mathcal{X})$, the probability of a model given the sample, and sample high probable models from this density.

Hansen and Salamon (1990) have shown that given independent two-class classifiers with success probability higher than 1/2, namely, better than random guessing, by taking a majority vote, the accuracy increases as the number of voting classifiers increases. Let us assume that d_j are iid with expected value $E[d_j]$ and variance $\text{Var}(d_j)$, then when we take a simple average with $w_j = 1/L$, the expected value and variance of the output are

$$\begin{aligned} E[y] &= E\left[\sum_j \frac{1}{L} d_j\right] = \frac{1}{L} LE[d_j] = E[d_j] \\ \text{Var}(y) &= \text{Var}\left(\sum_j \frac{1}{L} d_j\right) = \frac{1}{L^2}\text{Var}\left(\sum_j d_j\right) = \frac{1}{L^2} L\text{Var}(d_j) = \frac{1}{L}\text{Var}(d_j) \end{aligned} \tag{15.5}$$

We see that the expected value does not change, so the bias does not change. But variance, and therefore mean square error, decreases as the

number of independent voters, L, increases. In the general case,

$$\text{Var}(y) = \frac{1}{L^2}\text{Var}\left(\sum_j d_j\right) = \frac{1}{L^2}\left[\sum_j \text{Var}(d_j) + 2\sum_j \sum_{i<j} \text{Cov}(d_j, d_i)\right] \tag{15.6}$$

so we see that further decrease in variance is possible if the voters are not independent but are negatively correlated. The error then decreases if the accompanying increase in bias is not higher.

If we view each base-learner as a random noise function added to the true discriminant/regression function and if these noise functions are uncorrelated with 0 mean, then the averaging of the individual estimates is like averaging over the noise. In this sense, voting has the effect of smoothing in the functional space and can be thought of as a regularizer with a smoothness assumption on the true function (Perrone 1993). We saw an example of this in figure 4.5(d), where averaging over models with large variance, we get a better fit than those of the individual models. This is the idea in voting: We vote over models with high variance and low bias so that after combination, the bias remains small and we reduce the variance by averaging. Even if the individual models are biased, the decrease in variance may offset this bias and still a decrease in error is possible.

15.3 Error-Correcting Output Codes

ERROR-CORRECTING OUTPUT CODES

In *error-correcting output codes* (ECOC) (Dietterich and Bakiri 1995), the main classification task is defined in terms of a number of subtasks that are implemented by the base-learners. The idea is that the original task of separating one class from all other classes may be a difficult problem. Instead, we want to define a set of simpler classification problems, each specializing in one aspect of the task, and combining these simpler classifiers, we get the final classifier.

Base-learners are binary classifiers having output $-1/+1$, and there is a *code matrix* $\mathbf{W}$ of $K \times L$ whose K rows are the binary codes of classes in terms of the L base-learners d_j. For example, if the second row of $\mathbf{W}$ is $[-1, +1, +1, -1]$, this means that for us to say an instance belongs to C_2, the instance should be on the negative side of d_1 and d_4, and on the positive side of d_2 and d_3. Similarly, the columns of the code matrix defines the task of the base-learners. For example if the third column is $[-1, +1, +1]^T$, we understand that the task of the third base-learner,

d_3, is to separate the instances of C_1 from the instances of C_2 and C_3 combined. This is how we form the training set of the base-learners. For example in this case, all instances labeled with C_2 and C_3 form $\mathcal{X}_3^+$ and instances labeled with C_1 form $\mathcal{X}_3^-$, and d_3 is trained so that $x^t \in \mathcal{X}_3^+$ give output $+1$ and $x^t \in \mathcal{X}_3^-$ give output -1.

The code matrix thus allows us to define a polychotomy ($K > 2$ classification problem) in terms of dichotomies ($K = 2$ classification problem), and it is a method that is applicable using any learning algorithm to implement the dichotomizer base-learners—for example, linear or multilayer perceptrons (with a single output), decision trees, or SVMs whose original definition is for two-class problems.

The typical one discriminant per class setting corresponds to the diagonal code matrix where $L = K$. For example, for $K = 4$, we have

$$\mathbf{W} = \begin{bmatrix} +1 & -1 & -1 & -1 \\ -1 & +1 & -1 & -1 \\ -1 & -1 & +1 & -1 \\ -1 & -1 & -1 & +1 \end{bmatrix}$$

The problem here is that if there is an error with one of the base-learners, there is a misclassification because the class code words are so similar. So the approach in error-correcting codes is to have $L > K$ and increase the Hamming distance between the code words. One possibility is *pairwise separation* of classes where there is a separate base-learner to separate C_i from C_j, for $i < j$ (section 10.4). In this case, $L = K(K-1)/2$ and with $K = 4$, the code matrix is

$$\mathbf{W} = \begin{bmatrix} +1 & +1 & +1 & 0 & 0 & 0 \\ -1 & 0 & 0 & +1 & +1 & 0 \\ 0 & -1 & 0 & -1 & 0 & +1 \\ 0 & 0 & -1 & 0 & -1 & -1 \end{bmatrix}$$

where a zero entry denotes "don't care." That is, d_1 is trained to separate C_1 from C_2 and does not use the training instances belonging to the other classes. Similarly, we say that an instance belongs to C_2 if $d_1 = -1$ and $d_4 = d_5 = +1$, and we do not consider the values of d_2, d_3, and d_6. The problem here is that L is $\mathcal{O}(K^2)$, and for large K pairwise separation may not be feasible.

The approach is to set L beforehand and then find $\mathbf{W}$ such that the distances between rows, and at the same time the distances between columns, are as large as possible, in terms of Hamming distance. With

K classes, there are $2^{(K-1)} - 1$ possible columns, namely, two-class problems. This is because K bits can be written in 2^K different ways and complements (e.g., "0101" and "1010," from our point of view, define the same discriminant), dividing the possible combinations by 2 and then subtracting 1 because a column of all 0s (or 1s) is useless. For example, when $K = 4$, we have

$$\mathbf{W} = \begin{bmatrix} -1 & -1 & -1 & -1 & -1 & -1 & -1 \\ -1 & -1 & -1 & +1 & +1 & +1 & +1 \\ -1 & +1 & +1 & -1 & -1 & +1 & +1 \\ +1 & -1 & +1 & -1 & +1 & -1 & +1 \end{bmatrix}$$

When K is large, for a given value of L, we look for L columns out of the $2^{(K-1)}-1$. We would like these columns of $\mathbf{W}$ to be as different as possible so that the tasks to be learned by the base-learners are as different from each other as possible. At the same time, we would like the rows of $\mathbf{W}$ to be as different as possible so that we can have maximum error correction in case one or more base-learners fail.

ECOC can be written as a voting scheme where the entries of $\mathbf{W}$, w_{ij}, are considered as vote weights:

$$y_i = \sum_{j=1}^{L} w_{ij} d_j \tag{15.7}$$

and then we choose the class with the highest y_i. Taking a weighted sum and then choosing the maximum instead of checking for an exact match allows d_j to no longer need to be binary but to take a value between -1 and $+1$, carrying soft certainties instead of hard decisions. Note that a value p_j between 0 and 1, for example, a posterior probability, can be converted to a value d_j between -1 and $+1$ simply as

$$d_j = 2p_j - 1$$

The difference between equation 15.7 and the generic voting model of equation 15.3 is that the weights of votes can be different for different classes, namely, we no longer have w_j but w_{ij}, and also that $w_j \geq 0$ whereas w_{ij} are -1, 0, or $+1$.

One problem with ECOC is that because the code matrix $\mathbf{W}$ is set a priori, there is no guarantee that the subtasks as defined by the columns of $\mathbf{W}$ will be simple. Dietterich and Bakiri (1995) report that the dichotomizer trees may be larger than the polychotomizer trees and when multilayer perceptrons are used, there may be slower convergence by backpropagation.

15.4 Bagging

BAGGING

Bagging is a voting method whereby base-learners are made different by training them over slightly different training sets. Generating L slightly different samples from a given sample is done by bootstrap, where given a training set X of size N, we draw N instances randomly from X *with replacement* (section 14.2.3). Because sampling is done with replacement, it is possible that some instances are drawn more than once and that certain instances are not drawn at all. When this is done to generate L samples $X_j, j = 1,\ldots,L$, these samples are similar because they are all drawn from the same original sample, but they are also slightly different due to chance. The base-learners d_j are trained with these L samples X_j. A learning algorithm is an *unstable algorithm* if small changes in the training set causes a large difference in the generated learner, namely, the learning algorithm has high variance. Bagging, short for bootstrap aggregating, uses bootstrap to generate L training sets, trains L base-learners using an unstable learning procedure and then during testing, takes an average (Breiman 1996). Bagging can be used both for classification and regression. In the case of regression, to be more robust, one can take the median instead of the average when combining predictions.

UNSTABLE ALGORITHM

Algorithms such as decision trees and multilayer perceptrons are unstable. Nearest neighbor is stable but condensed nearest neighbor is unstable (Alpaydın 1997). If the original training set is large, then we may want to generate smaller sets of size $N' < N$ from them using bootstrap, since otherwise the bootstrap replicates X_j will be too similar, and d_j will be highly correlated.

15.5 Boosting

In bagging, generating complementary base-learners is left to chance and to the unstability of the learning method. In boosting, we actively try to generate complementary base-learners by training the next learner on the mistakes of the previous learners. The original *boosting* algorithm (Schapire 1990) combines three weak learners to generate a strong learner. A *weak learner* has error probability less than 1/2, which makes it better than random guessing on a two-class problem, and a *strong learner* has arbitrarily small error probability.

BOOSTING

WEAK LEARNER

STRONG LEARNER

Given a large training set, we randomly divide it into three. We use X_1

and train d_1. We then take $\mathcal{X}_2$ and feed it to d_1. We take all instances misclassified by d_1 and also as many instances on which d_1 is correct from $\mathcal{X}_2$, and these together form the training set of d_2. We then take $\mathcal{X}_3$ and feed it to d_1 and d_2. The instances on which d_1 and d_2 disagree form the training set of d_3. During testing, given an instance, we give it to d_1 and d_2; if they agree, that is the response, otherwise the response of d_3 is taken as the output. Schapire (1990) has shown that this overall system has reduced error rate, and the error rate can arbitrarily be reduced by using such systems recursively, that is, a boosting system of three models used as d_j in a higher system.

Though it is quite successful, the disadvantage of the boosting method is that it requires a very large training sample. The sample should be divided into three and furthermore, the second and third classifiers are only trained on a subset on which the previous ones err. So unless one has a quite large training set, d_2 and d_3 will not have training sets of reasonable size. Drucker et al. (1994) use a set of 118,000 instances in boosting multilayer perceptrons for optical handwritten digit recognition.

ADABOOST

Freund and Schapire (1996) proposed a variant, named *AdaBoost,* short for adaptive boosting, that uses the same training set over and over and thus need not be large. AdaBoost can also combine an arbitrary number of base-learners, not three.

Many variants of AdaBoost have been proposed; here, we discuss the original algorithm AdaBoost.M1 (see figure 15.2): The idea is to modify the probabilities of drawing the instances as a function of the error. Let us say p_j^t denotes the probability that the instance pair (x^t, r^t) is drawn to train the jth base-learner. Initially, all $p_1^t = 1/N$. Then we add new base-learners as follows, starting from $j = 1$: ϵ_j denotes the error rate of d_j. AdaBoost requires that $\epsilon_j < 1/2, \forall j$; if not, we stop adding new base-learners. Note that this error rate is not on the original problem but on the dataset used at step j. We define $\beta_j = \epsilon_j/(1 - \epsilon_j) < 1$, and we set $p_{j+1}^t = \beta_j p_j^t$ if d_j correctly classifies x^t, otherwise $p_{j+1}^t = p_j^t$. Because p_{j+1}^t should be probabilities, there is a normalization where we divide p_{j+1}^t by $\sum_t p_{j+1}^t$, so that they sum up to 1. This has the effect that the probability of a correctly classified instance is decreased, and the probability of a misclassified instance increases. Then a new sample of the same size is drawn from the original sample according to these modified probabilities, p_{j+1}^t, with replacement, and is used to train d_{j+1}.

This has the effect that d_{j+1} focuses more on instances misclassified

Training:
For all $\{x^t, r^t\}_{t=1}^N \in \mathcal{X}$, initialize $p_1^t = 1/N$
For all base-learners $j = 1, \ldots, L$
Randomly draw $\mathcal{X}_j$ from $\mathcal{X}$ with probabilities p_j^t
Train d_j using $\mathcal{X}_j$
For each (x^t, r^t), calculate $y_j^t \leftarrow d_j(x^t)$
Calculate error rate: $\epsilon_j \leftarrow \sum_t p_j^t \cdot 1(y_j^t \neq r^t)$
If $\epsilon_j > 1/2$, then $L \leftarrow j - 1$; stop
$\beta_j \leftarrow \epsilon_j / (1 - \epsilon_j)$
For each (x^t, r^t), decrease probabilities if correct:
If $y_j^t = r^t$ $p_{j+1}^t \leftarrow \beta_j p_j^t$ Else $p_{j+1}^t \leftarrow p_j^t$
Normalize probabilities:
$Z_j \leftarrow \sum_t p_{j+1}^t$; $p_{j+1}^t \leftarrow p_{j+1}^t / Z_j$
Testing:
Given x, calculate $d_j(x), j = 1, \ldots, L$
Calculate class outputs, $i = 1, \ldots, K$:
$y_i = \sum_{j=1}^L \left(\log \frac{1}{\beta_j}\right) d_{ji}(x)$

Figure 15.2 AdaBoost algorithm.

by d_j. That is why the base-learners are chosen to be simple and not accurate, since otherwise the next training sample would contain only a few outlier and noisy instances repeated many times over. For example, with decision trees, *decision stumps,* which are trees grown only one or two levels, are used. So it is clear that these would have bias but the decrease in variance is larger and the overall error decreases. An algorithm like the linear discriminant has low variance, and we cannot gain by AdaBoosting linear discriminants.

Once training is done, AdaBoost is a voting method. Given an instance, all d_j decide and a weighted vote is taken where weights are proportional to the base-learners' accuracies (on the training set): $w_j = \log(1/\beta_j)$. Freund and Schapire (1996) showed improved accuracy in twenty-two benchmark problems, equal accuracy in one problem, and worse accuracy in four problems.

Schapire et al. (1998) explain that the success of AdaBoost is due to its property of increasing the *margin.* If the margin increases, the training instances are better separated and an error is less likely. This makes

MARGIN

AdaBoost's aim similar to that of support vector machines (section 10.9).

In AdaBoost, although different base-learners have slightly different training sets, this difference is not left to chance as in bagging, but is a function of the error of the previous base-learner. The actual performance of boosting on a particular problem is clearly dependent on the data and the base-learner. There should be enough training data and the base-learner should be weak but not too weak, and boosting is especially susceptible to noise and outliers.

AdaBoost has also been generalized to regression: One straightforward way, proposed by Avnimelech and Intrator (1997), checks for whether the prediction error is larger than a certain threshold, and if so marks it as error, then uses AdaBoost proper. In another version (Drucker 1997), probabilities are modified based on the magnitude of error, such that instances where the previous base-learner commits a large error, have a higher probability of being drawn to train the next base-learner. Weighted average, or median, is used to combine the predictions of the base-learners.

15.6 Mixture of Experts Revisited

MIXTURE OF EXPERTS

In voting, the weights w_j are constant over the input space. In the *mixture of experts* architecture (section 12.8), there is a gating network whose outputs are taken as weights in voting. This architecture can then be viewed as a voting method where the votes depend on the input, and may be different for different inputs. The competitive learning algorithm used by the mixture of experts localizes the base-learners such that each of them becomes an expert in a different part of the input space and have its weight, $w_j(x)$, close to 1 in its region of expertise. The final output is a weighted average as in voting

$$y = \sum_{j=1}^{L} w_j(x) d_j \tag{15.8}$$

except in this case, both the base-learners and the weights are a function of the input (see figure 15.3).

Jacobs (1997) has shown that in the mixture of experts architecture, experts are biased but are negatively correlated. As training proceeds, bias decreases and expert variances increase but at the same time as experts localize in different parts of the input space, their covariances

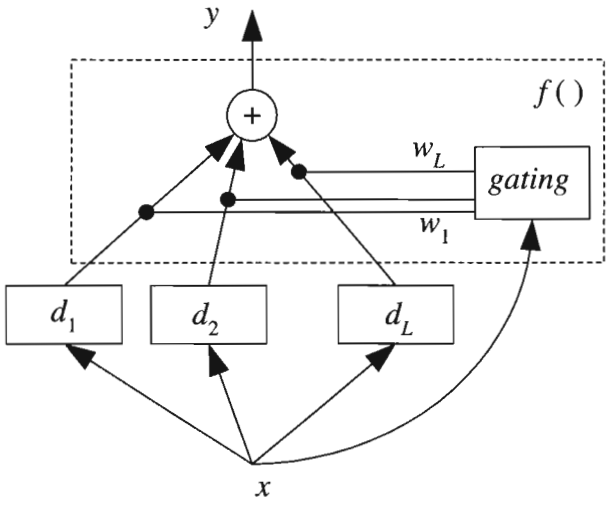

Figure 15.3 Mixture of experts is a voting method where the votes, as given by the gating system, are a function of the input. The combiner system f also includes this gating system.

get more and more negative, which, due to equation 15.6, decreases the total variance, and thus the error. In section 12.8, we considered the case where both are linear functions but a nonlinear method can also be used both for the experts and the gating. This would decrease the expert biases but risk increasing expert variances and overfitting.

15.7 Stacked Generalization

STACKED GENERALIZATION

Stacked generalization is a technique proposed by Wolpert (1992) that extends voting in that the way the output of the base-learners is combined need not be linear but is learned through a combiner system, $f(\cdot|\Phi)$, which is another learner, whose parameters Φ are also trained (see figure 15.4):

$$y = f(d_1, d_2, \ldots, d_L|\Phi) \tag{15.9}$$

The combiner learns what the correct output is when the base-learners give a certain output combination. We cannot train the combiner function

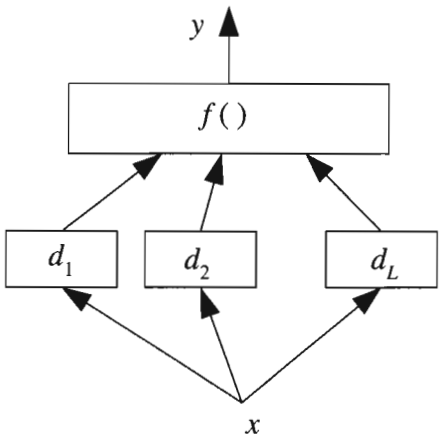

Figure 15.4 In stacked generalization, the combiner is another learner and is not restricted to being a linear combination as in voting.

on the training data because the base-learners may be memorizing the training set; the combiner system should actually learn how the base-learners make errors. Stacking is a means of estimating and correcting for the biases of the base-learners. Therefore the combiner should be trained on data unused in training the base-learners. Wolpert proposes to use leave-one-out though this is too costly and k-fold cross-validation is more efficient when we have a large sample.

If $f(\cdot|w_1,\ldots,w_L)$ is a linear model with constraints, $w_i \geq 0, \sum_j w_j = 1$, the optimal weights can be found by constrained regression. Note, however, that there is no restriction on the combiner function and unlike voting, the combination can be nonlinear. For example, $f(\cdot)$ may be a multilayer perceptron with Φ its connection weights. The outputs of the base-learners d_j define a new L-dimensional space in which the output discriminant/regression function is learned by the combiner function.

In stacked generalization, we would like the base-learners to be as different as possible so that they will complement each other, and it is advisable for them to be based on different learning algorithms. Zhang, Mesirov, and Waltz (1992) use stacking for protein secondary structure prediction with significant improvement in accuracy. In their study, the base-learners are a parametric classifier, a nearest-neighbor classifier,

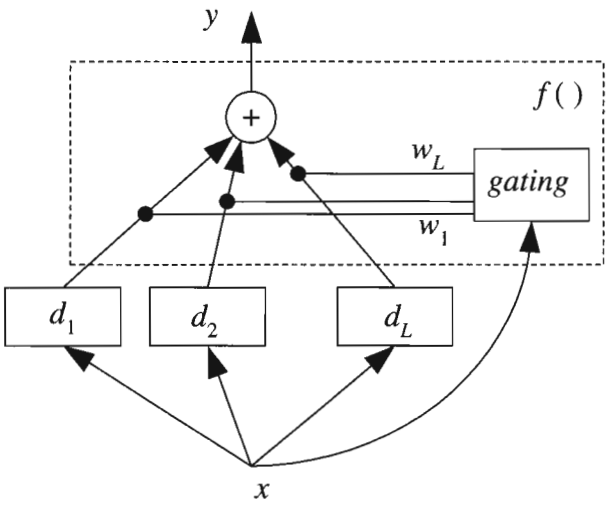

Figure 15.3 Mixture of experts is a voting method where the votes, as given by the gating system, are a function of the input. The combiner system f also includes this gating system.

get more and more negative, which, due to equation 15.6, decreases the total variance, and thus the error. In section 12.8, we considered the case where both are linear functions but a nonlinear method can also be used both for the experts and the gating. This would decrease the expert biases but risk increasing expert variances and overfitting.

15.7 Stacked Generalization

STACKED GENERALIZATION

Stacked generalization is a technique proposed by Wolpert (1992) that extends voting in that the way the output of the base-learners is combined need not be linear but is learned through a combiner system, $f(\cdot|\Phi)$, which is another learner, whose parameters Φ are also trained (see figure 15.4):

$$y = f(d_1, d_2, \ldots, d_L|\Phi) \tag{15.9}$$

The combiner learns what the correct output is when the base-learners give a certain output combination. We cannot train the combiner function

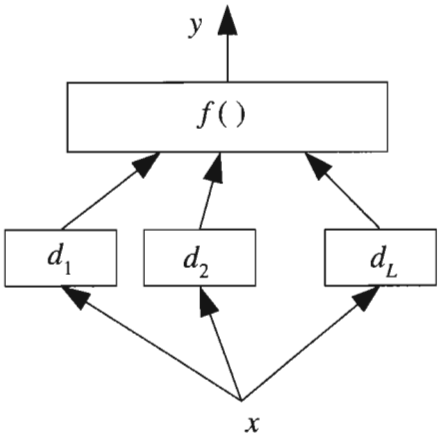

Figure 15.4 In stacked generalization, the combiner is another learner and is not restricted to being a linear combination as in voting.

on the training data because the base-learners may be memorizing the training set; the combiner system should actually learn how the base-learners make errors. Stacking is a means of estimating and correcting for the biases of the base-learners. Therefore the combiner should be trained on data unused in training the base-learners. Wolpert proposes to use leave-one-out though this is too costly and k-fold cross-validation is more efficient when we have a large sample.

If $f(\cdot|w_1,\ldots,w_L)$ is a linear model with constraints, $w_i \geq 0, \sum_j w_j = 1$, the optimal weights can be found by constrained regression. Note, however, that there is no restriction on the combiner function and unlike voting, the combination can be nonlinear. For example, $f(\cdot)$ may be a multilayer perceptron with Φ its connection weights. The outputs of the base-learners d_j define a new L-dimensional space in which the output discriminant/regression function is learned by the combiner function.

In stacked generalization, we would like the base-learners to be as different as possible so that they will complement each other, and it is advisable for them to be based on different learning algorithms. Zhang, Mesirov, and Waltz (1992) use stacking for protein secondary structure prediction with significant improvement in accuracy. In their study, the base-learners are a parametric classifier, a nearest-neighbor classifier,

and a multilayer perceptron. The combiner is another multilayer perceptron.

15.8 Cascading

CASCADING

The idea in cascaded classifiers is to have a *sequence* of base-classifiers d_j sorted in terms of their space or time complexity, or the cost of the representation they use, so that d_{j+1} is costlier than d_j (Kaynak and Alpaydın 2000). *Cascading* is a multistage method and we use d_j only if all preceding learners, $d_k, k < j$ are not confident (see figure 15.5). For this, associated with each learner is a *confidence* w_j such that we say d_j is confident of its output and can be used if $w_j > \theta_j$ where $1/K < \theta_j \leq \theta_{j+1} < 1$ is the confidence threshold. In classification, the confidence function is set to the highest posterior: $w_j \equiv \max_i d_{ji}$; this is the strategy used for rejections (section 3.3).

We use learner d_j if all the preceding learners are not confident:

$$y_i = d_{ji} \text{ if } w_j > \theta_j \text{ and } \forall k < j, w_k < \theta_k \tag{15.10}$$

Starting with $j = 1$, given a training set, we train d_j. Then we find all instances from a separate validation set on which d_j is not confident, and these constitute the training set of d_{j+1}. Note that unlike in AdaBoost, we choose not only the misclassified instances but the ones for which the previous base-learner is not confident. This covers the misclassifications as well as the instances for which the posterior is not high enough; these are instances on the right side of the boundary but for which the distance to the discriminant, namely, the margin, is not large enough.

The idea is that an early simple classifier handles the majority of instances, and a more complex classifier is only used for a small percentage, thereby not significantly increasing the overall complexity. This is contrary to the multiexpert methods like voting where all base-learners generate their output for any instance. If the problem space is complex, a few base-classifiers may be cascaded increasing the complexity at each stage. In order not to increase the number of base-classifiers, the few instances not covered by any are stored as they are and are treated by a nonparametric classifier, such as k-NN.

The inductive bias of cascading is that the classes can be explained by a small number of "rules" in increasing complexity, with an additional small set of "exceptions" not covered by the rules. The rules are implemented by simple base-classifiers, for example, perceptrons of increasing

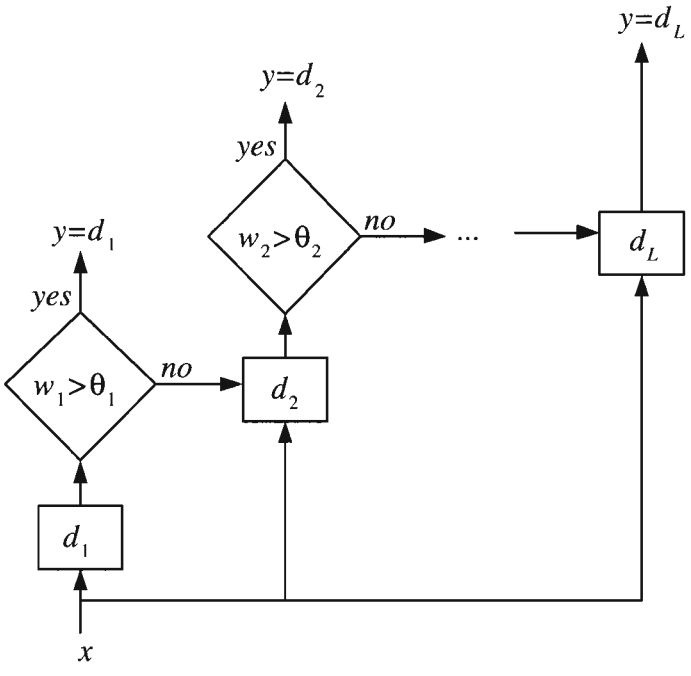

Figure 15.5 Cascading is a multistage method where there is a sequence of classifiers, and the next one is used only when the preceding ones are not confident.

complexity, which learn general rules valid over the whole input space. Exceptions are localized instances and are best handled by a nonparametric model.

Cascading thus stands between the two extremes of parametric and nonparametric classification. The former—for example, a linear model—finds a single rule that should cover all the instances. A nonparametric classifier—for example, k-NN—stores the whole set of instances without generating any simple rule explaining them. Cascading generates a rule (or rules) to explain a large part of the instances as cheaply as possible and stores the rest as exceptions. This makes sense in a lot of learning applications. For example, most of the time the past tense of a verb in English is found by adding a "-d" or "-ed" to the verb; there are also irregular verbs—for example, "go"/"went"—that do not obey this rule.

15.9 Notes

The idea in combining learners is to divide a complex task into simpler tasks that are handled by separately trained base-learners. Each base-learner has its own task. If we had a large learner containing all the base-learners, then it would risk overfitting. For example, consider taking a vote over three multilayer perceptrons, each with a single hidden layer. If we combine them all together with the linear model combining their outputs, this is a large multilayer perceptron with two hidden layers. If we train this large model with the whole sample, it very probably overfits. When we train the three multilayer perceptrons separately, for example, using ECOC, bagging, and so forth, it is as if we define a required output for the second-layer hidden nodes of the large multilayer perceptron. This puts a constraint on what the overall learner should learn and simplifies learning.

One disadvantage of combining is that the combined system is not interpretable. For example, even though decision trees are interpretable, bagged or boosted trees are not interpretable. Error-correcting codes with their weights as $-1/0/+1$ allow some form of interpretability. Mayoraz and Moreira (1997) discuss incremental methods for learning the error-correcting output codes where base-learners are added when needed. Allwein, Schapire, and Singer (2000) discuss various methods for coding multiclass problems as two-class problems. Alpaydın and Mayoraz (1999) consider the application of ECOC where linear base-learners are combined to get nonlinear discriminants, and they also propose methods to learn the ECOC matrix from data.

The earliest and most intuitive approach is voting. Xu, Krzyzak, and Suen (1992) is an early review. Benedikttson and Swain (1992) consider voting methods for combining multiple sources. Kittler et al. (1998) give a recent review of voting methods and also discuss an application where multiple representations are combined. The task is person identification using three representations: frontal face image, face profile image, and voice. The error rate of the voting model is lower than the error rates when a single representation is used. Another application is given in Alimoğlu and Alpaydın 1997 where for improved handwritten digit recognition, two sources of information are combined: One is the temporal pen movement data as the digit is written on a touch-sensitive pad, and the other is the static two-dimensional bitmap image once the digit is written. In that application, the two classifiers using either of the two

representations have around 5 percent error, but combining the two reduces the error rate to 3 percent. It is also seen that the critical stage is the design of the complementary learners and/or representations, the way they are combined is not as critical.

It has been shown by Jacobs (1995) that L dependent experts are worth the same as L' independent experts where $L' \leq L$. Under certain circumstances, voting models and Bayesian techniques will yield identical results (Jacobs 1995). The priors of equation 15.4 are in turn modeled as distributions with hyperparameters and in the ideal case, one should integrate over the whole model-parameter space. This approach is not generally feasible in practice and one resorts to approximation or sampling. With advances in Bayesian statistics, these supra-Bayesian techniques may become more important in the near future.

Combining multiple learners has been a popular topic in machine learning since early 1990s, and research has been going on ever since (Dietterich 1997). AdaBoost is currently considered to be one of the best machine learning algorithms and is almost automatic once the base-learner and the number of base-learners are chosen. There are also versions of AdaBoost where the next base-learner is trained on the residual of the previous base-learner (Hastie, Tibshirani, and Friedman 2001). There is a Web site www.boosting.org where recent publications on model combination in general and AdaBoost in particular could be found. Despite the success of multiple models in practice, there is still discussion going on as to how or why model combination works; for example, see Breiman 1998; Bauer and Kohavi 1999.

15.10 Exercises

1. If each base-learner is iid and correct with probability $p > 1/2$, what is the probability that a majority vote over L classifiers gives the correct answer?
2. In bagging, to generate the L training sets, what would be the effect of using L-fold cross-validation instead of bootstrap?
3. Propose an incremental algorithm for learning error-correcting output codes where new two-class problems are added as they are needed to better solve the multiclass problem.
4. What is the difference between voting and stacking using a linear perceptron as the combiner function?
5. In cascading, why do we require $\theta_{j+1} \geq \theta_j$?

16 *Reinforcement Learning*

In reinforcement learning, the learner is a decision-making agent that takes actions in an environment and receives reward (or penalty) for its actions in trying to solve a problem. After a set of trial-and-error runs, it should learn the best policy, which is the sequence of actions that maximize the total reward.

16.1 Introduction

LET US SAY we want to build a machine that learns to play chess. In this case we cannot use a supervised learner for two reasons: First, it is very costly to have a teacher that will take us through many games and indicate us the best move for each position. Second, in many cases, there is no such thing as the best move; the goodness of a move depends on the moves that follow. A single move does not count; a sequence of moves is good if after playing them we win the game. The only feedback is at the end of the game when we win or lose the game.

Another example is a robot that is placed in a maze. The robot can move in one of the four compass directions and should make a sequence of movements to reach the exit. As long as the robot is in the maze, there is no feedback and the robot tries many moves until it reaches the exit and only then does it get a reward. In this case there is no opponent, but we can have a preference for shorter trajectories implying that in this case we play against time.

These two applications have a number of points in common: There is a decision maker, called the *agent,* that is placed in an *environment* (see figure 16.1). In chess, the game-player is the decision maker and the environment is the board; in the second case, the maze is the environment

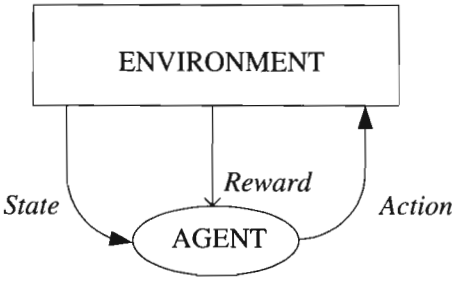

Figure 16.1 The agent interacts with an environment. At any state of the environment, the agent takes an action that changes the state and returns a reward.

of the robot. At any time, the environment is in a certain *state* that is one of a set of possible states—for example, the state of the board, the position of the robot in the maze. The decision maker has a set of *actions* possible: legal movement of pieces on the chess board, movement of the robot in possible directions without hitting the walls, and so forth. Once an action is chosen and taken, the state changes. The solution to the task requires a sequence of actions and we get feedback, in the form of a *reward* rarely, generally only when the complete sequence is carried out. The reward defines the problem and is necessary if we want a *learning* agent. The learning agent learns the best sequence of actions to solve a problem where "best" is quantified as the sequence of actions that has the maximum cumulative reward. Such is the setting of *reinforcement learning.*

Reinforcement learning is different from the learning methods we discussed before in a number of respects: It is called "learning with a critic," as opposed to learning with a teacher which we have in supervised learning. A *critic* differs from a teacher in that it does not tell us what to do but only how well we have been doing in the past; the critic never informs in advance. The feedback from the critic is scarce and when it comes, it comes late. This leads to the *credit assignment* problem: After taking several actions and getting the reward, we would like to assess the individual actions we did in the past and find the moves that led us to win the reward so that we can record and recall them later on. As we see shortly, what a reinforcement learning program does is that it learns to generate an *internal value* for the intermediate states or actions as to how good they are in leading us to the goal and getting us to the real reward. Once

CRITIC

CREDIT ASSIGNMENT

such an internal reward mechanism is learned, the agent can just take the local actions to maximize it.

The solution to the task requires a *sequence* of actions and from this perspective, we remember the Markov models we discussed in chapter 13. Indeed, we use a Markov decision process to model the agent. The difference is that in the case of Markov models, there is an external process that generates a sequence of signals, for example, speech, which we observe and model. In the current case, however, it is the agent that generates the sequence of actions. Previously, we also made a distinction between observable and hidden Markov models where the states are observed or hidden (and should be inferred) respectively. Similarly here, sometimes we have a partially observable Markov decision process in cases where the agent does not know its state exactly but should infer it with some uncertainty through observations using sensors. For example, in the case of a robot moving in a room, the robot may not know its exact position in the room, nor the exact location of obstacles nor the goal, and should make decisions through a limited image provided by a camera.

16.2 Single State Case: *K*-Armed Bandit

K-ARMED BANDIT

We start with a simple example. The *K-armed bandit* is a hypothetical slot machine with K levers. The action is to choose and pull one of the levers, and we win a certain amount of money that is the reward associated with the lever (action). The task is to decide which lever to pull to maximize the reward. This is a clasification problem where we choose one of K. If this were supervised learning, then the teacher would tell us the correct class, namely, the lever leading to maximum earning. In this case of reinforcement learning, we can only try different levers and keep track of the best. This is a simplified reinforcement learning problem because there is only one state, or one slot machine, and we need only decide on the action. Another reason why this is simplified is that we immediately get a reward after a single action; the reward is not delayed so we immediately see the value of our action.

Let us say $Q(a)$ is the value of action a. Initially, $Q(a) = 0$ for all a. When we try action a, we get reward $r_a \geq 0$. If rewards are deterministic, we always get the same r_a for any pull of a and in such a case, we can just set $Q(a) = r_a$. If we want to exploit, once we find an action a such that $Q(a) > 0$, we can keep choosing it and get r_a at each pull. However,

it is quite possible that there is another lever with a higher reward, so we need to explore.

We can choose different actions and store $Q(a)$ for all a. Whenever we want to exploit, we can choose the action with the maximum value, that is,

$$\text{choose } a^* \text{ if } Q(a^*) = \max_a Q(a) \tag{16.1}$$

If rewards are not deterministic but stochastic, we get a different reward each time we choose the same action. The amount of reward is defined by the probability distribution $p(r|a)$. In such a case, we define $Q_t(a)$ as the estimate of the value of action a at time t. It is an average of all rewards received when action a was chosen before time t. An online update can be defined as

$$Q_{t+1}(a) \leftarrow Q_t(a) + \eta[r_{t+1}(a) - Q_t(a)] \tag{16.2}$$

where $r_{t+1}(a)$ is the reward received after taking action a at time $(t+1)$st time.

Note that equation 16.2 is the *delta rule* that we have used on many occasions in the previous chapters: η is the learning factor (gradually decreased in time for convergence), r_{t+1} is the desired output, and $Q_t(a)$ is the current prediction. $Q_{t+1}(a)$ is the *expected* value of action a at time $t+1$ and converges to the mean of $p(r|a)$ as t increases.

The full reinforcement learning problem generalizes this simple case in a number of ways: First, we have several states. This corresponds to having several slot machines with different reward probabilities, $p(r|s_i, a_j)$, and we need to learn $Q(s_i, a_j)$, which is the value of taking action a_j when in state s_i. Second, the actions affect not only the reward but also the next state, and we move from one state to another. Third, the rewards are delayed and we need to be able to estimate immediate values from delayed rewards.

16.3 Elements of Reinforcement Learning

The learning decision maker is called the *agent*. The agent interacts with the *environment* that includes everything outside the agent. The agent has sensors to decide on its *state* in the environment and takes an *action* that modifies its state. When the agent takes an action, the environment provides a *reward*. Time is discrete as $t = 0, 1, 2, \ldots$ and $s_t \in S$ denotes

the state of the agent at time t where S is the set of all possible states. $a_t \in \mathcal{A}(s_t)$ denotes the action that the agent takes at time t where $\mathcal{A}(s_t)$ is the set of possible actions in state s_t. When the agent in state s_t takes the action a_t, the clock ticks, reward $r_{t+1} \in \Re$ is received, and the agent moves to the next state, s_{t+1}. The problem is modeled using a *Markov decision process* (MDP). The reward and next state are sampled from their respective probability distributions, $p(r_{t+1}|s_t, a_t)$ and $P(s_{t+1}|s_t, a_t)$. Note that what we have is a *Markov* system where the state and reward in the next time step depend only on the current state and action. In some applications, reward and next state are deterministic and for a certain state and action taken, there is one possible reward value and next state.

MARKOV DECISION PROCESS

Depending on the application, a certain state may be designated as the initial state and in some applications, there is also an absorbing terminal (goal) state where the search ends; all actions in this terminal state transition to itself with probability 1 and without any reward. The sequence of actions from the start to the terminal state is an *episode,* or a *trial.*

EPISODE

POLICY

The *policy,* π, defines the agent's behavior and is a mapping from the states of the environment to actions: $\pi : S \rightarrow \mathcal{A}$. The policy defines the action to be taken in any state s_t: $a_t = \pi(s_t)$. The *value* of a policy π, $V^\pi(s_t)$, is the expected cumulative reward that will be received while the agent follows the policy, starting from state s_t.

FINITE-HORIZON

In the *finite-horizon* or *episodic* model, the agent tries to maximize the expected reward for the next T steps:

$$V^\pi(s_t) = E[r_{t+1} + r_{t+2} + \cdots + r_{t+T}] = E\left[\sum_{i=1}^{T} r_{t+i}\right] \tag{16.3}$$

INFINITE-HORIZON

Certain tasks are continuing, and there is no prior fixed limit to the episode. In the *infinite-horizon* model, there is no sequence limit, but future rewards are discounted:

$$V^\pi(s_t) = E[r_{t+1} + \gamma r_{t+2} + \gamma^2 r_{t+3} + \cdots] = E\left[\sum_{i=1}^{\infty} \gamma^{i-1} r_{t+i}\right] \tag{16.4}$$

DISCOUNT RATE

where $0 \leq \gamma < 1$ is the *discount rate* to keep the return finite. If $\gamma = 0$, then only the immediate reward counts. As γ approaches 1, rewards further in the future count more, and we say that the agent becomes more farsighted. γ is less than 1 because there generally is a time limit to the sequence of actions needed to solve the task. The agent may be a robot that runs on a battery. We prefer rewards sooner rather than later because we are not certain how long we will survive.

OPTIMAL POLICY

For each policy π, there is a $V^{\pi}(s_t)$, and we want to find the *optimal policy* π^* such that

$$V^*(s_t) = \max_{\pi} V^{\pi}(s_t), \forall s_t \tag{16.5}$$

In some applications, for example, in control, instead of working with the values of states, $V(s_t)$, we prefer to work with the values of state-action pairs, $Q(s_t, a_t)$. $V(s_t)$ denotes how good it is for the agent to be in state s_t, whereas $Q(s_t, a_t)$ denotes how good it is to perform action a_t when in state s_t. We define $Q^*(s_t, a_t)$ as the value, that is, the expected cumulative reward, of action a_t taken in state s_t and then obeying the optimal policy afterward. The value of a state is equal to the value of the best possible action:

$$\begin{aligned} V^*(s_t) &= \max_{a_t} Q^*(s_t, a_t) \\ &= \max_{a_t} E\left[\sum_{i=1}^{\infty} \gamma^{i-1} r_{t+i}\right] \\ &= \max_{a_t} E\left[r_{t+1} + \gamma \sum_{i=1}^{\infty} \gamma^{i-1} r_{t+i+1}\right] \\ &= \max_{a_t} E\left[r_{t+1} + \gamma V^*(s_{t+1})\right] \end{aligned}$$

$$V^*(s_t) = \max_{a_t} \left(E[r_{t+1}] + \gamma \sum_{s_{t+1}} P(s_{t+1}|s_t, a_t) V^*(s_{t+1})\right) \tag{16.6}$$

To each possible next state s_{t+1}, we move with probability $P(s_{t+1}|s_t, a_t)$, and continuing from there using the optimal policy, the expected cumulative reward is $V^*(s_{t+1})$. We sum over all such possible next states, and we discount it because it is one time step later. Adding our immediate expected reward, we get the total expected cumulative reward for action a_t. We then choose the best of possible actions. Equation 16.6 is known as *Bellman's equation* (Bellman 1957). Similarly, we can also write

BELLMAN'S EQUATION

$$Q^*(s_t, a_t) = E[r_{t+1}] + \gamma \sum_{s_{t+1}} P(s_{t+1}|s_t, a_t) \max_{a_{t+1}} Q^*(s_{t+1}, a_{t+1}) \tag{16.7}$$

Once we have $Q^*(s_t, a_t)$ values, we can then define our policy π as taking the action a_t^* which has the highest value among all $Q^*(s_t, a_t)$:

$$\pi^*(s_t) : \text{Choose } a_t^* \text{ where } Q^*(s_t, a_t^*) = \max_{a_t} Q^*(s_t, a_t) \tag{16.8}$$

```
Initialize V(s) to arbitrary values
Repeat
    For all s ∈ S
        For all a ∈ A
            Q(s, a) ← E[r|s, a] + γ Σ_{s'∈S} P(s'|s, a)V(s')
        V(s) ← max_a Q(s, a)
Until V(s) converge
```

Figure 16.2 Value iteration algorithm for model-based learning.

This means that if we have the $Q^*(s_t, a_t)$ values, then by using a greedy search at each *local* step we get the optimal sequence of steps that maximizes the *cumulative* reward.

16.4 Model-Based Learning

We start with model-based learning where we completely know the environment model parameters, $p(r_{t+1}|s_t, a_t)$ and $P(s_{t+1}|s_t, a_t)$. In such a case, we do not need any exploration and can directly solve for the optimal value function and policy using dynamic programming. The optimal value function is unique and is the solution to the simultaneous equations given in equation 16.6. Once we have the optimal value function, the optimal policy is to choose the action that maximizes the value in the next state:

$$\pi^*(s_t) = \arg\max_{a_t} \left(E[r_{t+1}|s_t, a_t] + \gamma \sum_{s_{t+1} \in S} P(s_{t+1}|s_t, a_t) V^*(s_t) \right) \tag{16.9}$$

16.4.1 Value Iteration

VALUE ITERATION

To find the optimal policy, we can use the optimal value function, and there is an iterative algorithm called *value iteration* that has been shown to converge to the correct V^* values. Its pseudocode is given in figure 16.2.

We say that the values converged if the maximum value difference between two iterations is less than a certain threshold δ:

$$\max_{s \in S} |V^{(l+1)}(s) - V^{(l)}(s)| < \delta$$

Initialize a policy π arbitrarily
Repeat
  $\pi \leftarrow \pi'$
  Compute the values using π by
    solving the linear equations
      $V^{\pi}(s) = E[r|s, \pi(s)] + \gamma \sum_{s' \in S} P(s'|s, \pi(s)) V^{\pi}(s')$
  Improve the policy at each state
    $\pi'(s) \leftarrow \arg\max_a (E[r|s, a] + \gamma \sum_{s' \in S} P(s'|s, a) V^{\pi}(s'))$
Until $\pi = \pi'$

Figure 16.3 Policy iteration algorithm for model-based learning.

where l is the iteration counter. Because we only care for the actions with the maximum value, it is possible that the policy converges to the optimal one even before the values converge to their optimal values. Each iteration is $\mathcal{O}(|S|^2|\mathcal{A}|)$, but frequently there is only a small number $k < |S|$ of next possible states, so complexity decreases to $\mathcal{O}(k|S||\mathcal{A}|)$.

16.4.2 Policy Iteration

In policy iteration, we store and update the policy rather than doing this indirectly over the values. The pseudocode is given in figure 16.3. The idea is to start with a policy and improve it repeatedly until there is no change. The value function can be calculated by solving for the linear equations. We then check whether we can improve the policy by taking these into account. This step is guaranteed to improve the policy, and when no improvement is possible, the policy is guaranteed to be optimal. Each iteration of this algorithm takes $\mathcal{O}(|\mathcal{A}||S|^2 + |S|^3)$ time that is more than that of value iteration, but policy iteration needs fewer iterations than value iteration.

16.5 Temporal Difference Learning

Model is defined by the reward and next state probability distributions, and as we saw in section 16.4, when we know these, we can solve for the optimal policy using dynamic programming. However, these methods are costly, and we seldom have such perfect knowledge of the environment.

The more interesting and realistic application of reinforcement learning is when we do not have the model. This requires exploration of the environment to query the model. We first discuss how this exploration is done and later see model-free learning algorithms for deterministic and nondeterministic cases. Though we are not going to assume a full knowledge of the environment model, we will however require that it be stationary.

As we will see shortly, when we explore and get to see the value of the next state and reward, we use this information to update the value of the current state. These algorithms are called *temporal difference* algorithms because what we do is look at the difference between our current estimate of the value of a state (or a state-action pair) and the discounted value of the next state and the reward received.

TEMPORAL DIFFERENCE

16.5.1 Exploration Strategies

To explore, one possibility is to use *ϵ-greedy* search where with probability ϵ, we choose one action uniformly randomly among all possible actions, namely, explore, and with probability $1 - \epsilon$, we choose the best action, namely, exploit. We do not want to continue exploring indefinitely but start exploiting once we do enough exploration; for this, we start with a high ϵ value and gradually decrease it. We need to make sure that our policy is *soft*, that is, the probability of choosing any action $a \in \mathcal{A}$ in state $s \in S$ is greater than 0.

We can choose probabilistically, using the softmax function to convert values to probabilities

$$P(a|s) = \frac{\exp Q(s,a)}{\sum_{b=1}^{\mathcal{A}} \exp Q(s,b)} \tag{16.10}$$

and then sample according to these probabilities. To gradually move from exploration to exploitation, we can use a "temperature" variable T and define the probability of choosing action a as

$$P(a|s) = \frac{\exp[Q(s,a)/T]}{\sum_{b=1}^{\mathcal{A}} \exp[Q(s,b)/T]} \tag{16.11}$$

When T is large, all probabilities are equal and we have exploration. When T is small, better actions are favored. So the strategy is to start with a large T and decrease it gradually, a procedure named *annealing*, which in this case moves from exploration to exploitation smoothly in time.

16.5.2 Deterministic Rewards and Actions

In model-free learning, we first discuss the simpler deterministic case, where at any state-action pair, there is a single reward and next state possible. In this case, equation 16.7 reduces to

$$Q(s_t, a_t) = r_{t+1} + \gamma \max_{a_{t+1}} Q(s_{t+1}, a_{t+1}) \tag{16.12}$$

and we simply use this as an assignment to update $Q(s_t, a_t)$. When in state s_t, we choose action a_t by one of the stochastic strategies we saw earlier, which returns a reward r_{t+1} and takes us to state s_{t+1}. We then update the value of *previous* action as

$$\hat{Q}(s_t, a_t) \leftarrow r_{t+1} + \gamma \max_{a_{t+1}} \hat{Q}(s_{t+1}, a_{t+1}) \tag{16.13}$$

where the hat denotes that the value is an estimate. $\hat{Q}(s_{t+1}, a_{t+1})$ is a later value and has a higher chance of being correct. We discount this by γ and add the immediate reward (if any) and take this as the new estimate for the previous $\hat{Q}(s_t, a_t)$. This is called a *backup* because it can be viewed as taking the estimated value of an action in the next time step and "backing it up" to revise the estimate for the value of a current action.

BACKUP

For now we assume that all $\hat{Q}(s, a)$ values are stored in a table; we will see later on how we can store this information more succintly when $|S|$ and $|\mathcal{A}|$ are large.

Initially all $\hat{Q}(s_t, a_t)$ are 0 and they are updated in time as a result of trial episodes. Let us say we have a sequence of moves and at each move, we use equation 16.13 to update the estimate of the Q value of the previous state-action pair using the Q value of the current state-action pair. In the intermediate states, all rewards and therefore values are 0 so no update is done. When we get to the goal state, we get the reward r and then we can update the Q value of the previous state-action pair as γr. As for the preceding state-action pair, its immediate reward is 0 and the contribution from the next state-action pair is discounted by γ because it is one step later. Then in another episode, if we reach this state, we can update the one preceding that as $\gamma^2 r$, and so on. This way, after many episodes, this information is backed up to earlier state-action pairs. Q values increase until their optimal values as we find paths with higher cumulative reward, for example, shorter paths, but they never decrease (see figure 16.4).

Note that we do not know the reward or next state functions here. They are part of the environment, and it is as if we query them when

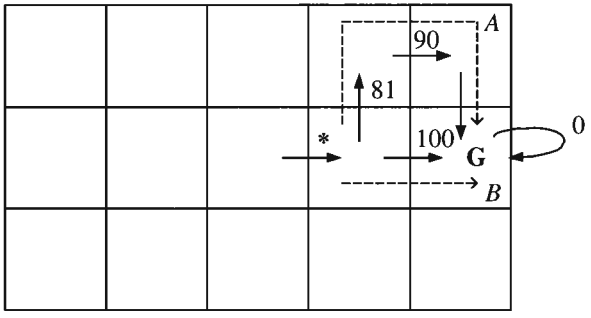

Figure 16.4 Example to show that Q values increase but never decrease. This is a deterministic grid-world where G is the goal state with reward 100, all other immediate rewards are 0 and $\gamma = 0.9$. Let us consider the Q value of the transition marked by asterisk, and let us just consider only the two paths A and B. Let us say that path A is seen before path B, then we have $\gamma \max(0, 81) = 72.9$. If afterward B is seen, a shorter path is found and the Q value becomes $\gamma \max(100, 81) = 90$. If B is seen before A, the Q value is $\gamma \max(100, 0) = 90$. Then when B is seen, it does not change because $\gamma \max(100, 81) = 90$.

we explore. We are not modeling them either, though that is another possibility. We just accept them as given and learn directly the optimal policy through the estimated value function.

16.5.3 Nondeterministic Rewards and Actions

If the rewards and the result of actions are not deterministic, then we have a probability distribution for the reward $p(r_{t+1}|s_t, a_t)$ from which rewards are sampled, and there is a probability distribution for the next state $P(s_{t+1}|s_t, a_t)$. These help us model the uncertainty in the system that may be due to forces we cannot control in the environment: for example, our opponent in chess, the dice in backgammon, or our lack of knowledge of the system. For example, we may have an imperfect robot which sometimes fails to go in the intended direction and deviates, or advances shorter or longer than expected.

In such a case, we have

$$Q(s_t, a_t) = E[r_{t+1}] + \gamma \sum_{s_{t+1}} P(s_{t+1}|s_t, a_t) \max_{a_{t+1}} Q(s_{t+1}, a_{t+1}) \tag{16.14}$$

We cannot do a direct assignment in this case because for the same

```
Initialize all Q(s, a) arbitrarily
For all episodes
    Initalize s
    Repeat
        Choose a using policy derived from Q, e.g., ε-greedy
        Take action a, observe r and s'
        Update Q(s, a):
            Q(s, a) ← Q(s, a) + η(r + γ max_a' Q(s', a') − Q(s, a))
        s ← s'
    Until s is terminal state
```

Figure 16.5 Q learning, which is an off-policy temporal difference algorithm.

state and action, we may receive different rewards or move to different next states. What we do is keep a running average. This is known as the

Q LEARNING

Q learning algorithm:

$$\hat{Q}(s_t, a_t) \leftarrow \hat{Q}(s_t, a_t) + \eta(r_{t+1} + \gamma \max_{a_{t+1}} \hat{Q}(s_{t+1}, a_{t+1}) - Q(s_t, a_t)) \tag{16.15}$$

We think of $r_{t+1} + \gamma \max_{a_{t+1}} \hat{Q}(s_{t+1}, a_{t+1})$ values as a sample of instances for each (s_t, a_t) pair and we would like $\hat{Q}(s_t, a_t)$ to converge to its mean. As usual η is gradually decreased in time for convergence, and it has been shown that this algorithm converges to the optimal Q^* values (Watkins and Dayan 1992). The pseudocode of Q learning algorithm is given in figure 16.5.

We can also think of equation 16.15 as reducing the difference between the current Q value and the backed up estimate, from one time step later. Such algorithms are called *temporal difference* (TD) algorithms (Sutton 1988).

TEMPORAL DIFFERENCE

OFF-POLICY

ON-POLICY

This is an *off-policy* method as the value of the best next action is used without using the policy. In an *on-policy* method, the policy is used to determine also the next action. The on-policy version of Q learning is the

SARSA

Sarsa algorithm whose pseudocode is given in figure 16.6. We see that instead of looking for all possible next actions a' and choosing the best, the on-policy Sarsa uses the policy derived from Q values to choose one next action a' and uses its Q value to calculate the temporal difference. On-policy methods estimate the value of a policy while using it to take actions. In off-policy methods, these are separated, and the policy used to generate behavior, called the *behavior* policy, may in fact be differ-

```
Initialize all Q(s,a) arbitrarily
For all episodes
    Initalize s
    Choose a using policy derived from Q, e.g., ε-greedy
    Repeat
        Take action a, observe r and s'
        Choose a' using policy derived from Q, e.g., ε-greedy
        Update Q(s,a):
            Q(s,a) ← Q(s,a) + η(r + γQ(s',a') − Q(s,a))
        s ← s', a ← a'
    Until s is terminal state
```

Figure 16.6 Sarsa algorithm, which is an on-policy version of Q learning.

ent from the policy that is evaluated and improved, called the *estimation* policy.

Sarsa converges with probability 1 to the optimal policy and state-action values if a *GLIE policy* is employed to choose actions. A GLIE (Greedy in the Limit with Infinite Exploration) policy is where (1) all state-action pairs are visited an infinite number of times, and (2) the policy converges in the limit to the greedy policy (which can be arranged, for example, with ϵ-greedy policies by setting $\epsilon = 1/t$).

TD LEARNING

The same idea of temporal difference can also be used to learn $V(s)$ values, instead of $Q(s,a)$. *TD learning* (Sutton 1988) uses the following update rule to update a state value:

$$V(s_t) \leftarrow V(s_t) + \eta[r_{t+1} + \gamma V(s_{t+1}) - V(s_t)] \tag{16.16}$$

This again is the delta rule where $r_{t+1} + \gamma V(s_{t+1})$ is the better, later prediction and $V(s_t)$ is the current estimate. Their difference is the temporal difference and the update is done to decrease this difference. The update factor η is gradually decreased, and TD is guaranteed to converge to the optimal value function $V^*(s)$.

16.5.4 Eligibility Traces

The previous algorithms are one-step, that is the temporal difference is used to update only the previous value (of the state or state-action pair).

ELIGIBILITY TRACE

An *eligibility trace* is a record of the occurrence of past visits and en-

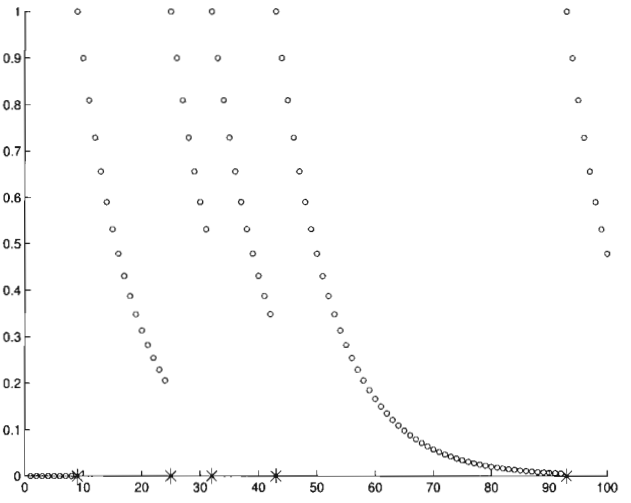

Figure 16.7 Example of an eligibility trace for a value. Visits are marked by an asterisk.

ables us to implement temporal credit assignment, allowing us to update the values of previously occurring visits as well. We discuss how this is done with Sarsa to learn Q values; adapting this to learn V values is straightforward.

To store the eligibility trace, we require an additional memory variable associated with each state-action pair, $e(s,a)$, initialized to 0. When the state-action pair (s,a) is visited, namely, when we take action a in state s, its eligibility is set to 1; the eligibilities of all other state-action pairs are multiplied by $\gamma\lambda$. $0 \leq \lambda \leq 1$ is the trace decay parameter.

$$e_t(s,a) = \begin{cases} 1 & \text{if } s = s_t \text{ and } a = a_t, \\ \gamma\lambda e_{t-1}(s,a) & \text{otherwise} \end{cases} \tag{16.17}$$

If a state-action pair has never been visited, its eligibility remains 0; if it has been, as time passes and other state-actions are visited, its eligibility decays depending on the value of γ and λ (see figure 16.7).

We remember that in Sarsa, the temporal error at time t is

$$\delta_t = r_{t+1} + \gamma Q(s_{t+1}, a_{t+1}) - Q(s_t, a_t) \tag{16.18}$$

In Sarsa with an eligibility trace, named Sarsa(λ), *all* state-action pairs

Initialize all $Q(s,a)$ arbitrarily, $e(s,a) \leftarrow 0, \forall s,a$
For all episodes
  Initalize s
  Choose a using policy derived from Q, e.g., ϵ-greedy
  Repeat
    Take action a, observe r and s'
    Choose a' using policy derived from Q, e.g., ϵ-greedy
    $\delta \leftarrow r + \gamma Q(s',a') - Q(s,a)$
    $e(s,a) \leftarrow 1$
    For all s,a:
      $Q(s,a) \leftarrow Q(s,a) + \eta\delta e(s,a)$
      $e(s,a) \leftarrow \gamma\lambda e(s,a)$
    $s \leftarrow s'$, $a \leftarrow a'$
  Until s is terminal state

Figure 16.8 Sarsa(λ) algorithm.

are updated as

$$Q(s,a) \leftarrow Q(s,a) + \eta\delta_t e_t(s,a), \ \forall s,a \tag{16.19}$$

This updates all eligible state-action pairs, where the update depends on how far they have occurred in the past. The value of λ defines the temporal credit: If $\lambda = 0$, only one-step update is done. The algorithms we discussed in section 16.5.3 are such and for this reason they are named $Q(0)$, Sarsa(0), or TD(0). As λ gets closer to 1, more of the previous steps are considered. When $\lambda = 1$, all previous steps are updated and the credit given to them falls only by γ per step. In online updating, all eligible values are updated immediately after each step; in offline updating, the updates are accumulated and a single update is done at the end of the episode. Online updating takes more time but converges faster.

SARSA(λ) The pseudocode for *Sarsa*(λ) is given in figure 16.8. $Q(\lambda)$ and TD(λ) algorithms can similarly be derived (Sutton and Barto 1998).

16.6 Generalization

Until now, we assumed that the $Q(s,a)$ values (or $V(s)$, if we are estimating values of states) are stored in a lookup table, and the algorithms

we considered earlier are called *tabular* algorithms. There are a number of problems with this approach: (1) When the number of states and the number of actions is large, the size of the table may become quite large; (2) States and actions may be continuous, for example, turning the steering wheel by a certain angle, and to use a table, they should be discretized which may cause error; (3) When the search space is large, too many episodes may be needed to fill in all the entries of the table with acceptable accuracy.

Instead of storing the Q values as they are, we can consider this a regression problem. This is a supervised learning problem where we define a regressor $Q(s, a|\boldsymbol{\theta})$, taking s and a as inputs and parameterized by a vector of parameters, $\boldsymbol{\theta}$, to learn Q values. For example, this can be an artificial neural network with s and a as its inputs, one output, and $\boldsymbol{\theta}$ its connection weights.

A good function approximator has the usual advantages and solves the problems discussed previously: A good approximation may be achieved with a simple model without explicitly storing the training instances; it can use continuous inputs; and it allows generalization: If we know that similar (s, a) pairs have similar Q values, we can generalize from past cases and come up with good $Q(s, a)$ values even if that state-action pair has never been encountered before.

To be able to train the regressor we need a training set. In the case of Sarsa(0), we saw before that we would like $Q(s_t, a_t)$ to get close to $r_{t+1} + \gamma Q(s_{t+1}, a_{t+1})$. So, we can form a set of training samples where the input is the state-action pair (s_t, a_t) and the required output is $r_{t+1} + \gamma Q(s_{t+1}, a_{t+1})$. We can write the squared error as

$$E^t(\boldsymbol{\theta}) = [r_{t+1} + \gamma Q(s_{t+1}, a_{t+1}) - Q(s_t, a_t)]^2 \tag{16.20}$$

Training sets can similarly be defined for $Q(0)$ and TD(0), where in the latter case we learn $V(s)$, and the required output is $r_{t+1} - \gamma V(s_{t+1})$. Once such a set is ready, we can use any supervised learning algorithm for learning the training set.

If we are using a gradient-descent method, as in training neural networks, the parameter vector is updated as

$$\Delta\boldsymbol{\theta} = \eta[r_{t+1} + \gamma Q(s_{t+1}, a_{t+1}) - Q(s_t, a_t)]\nabla_{\boldsymbol{\theta}_t} Q(s_t, a_t) \tag{16.21}$$

This is a one-step update. In the case of Sarsa(λ), the eligibility trace is also taken into account:

$$\Delta\boldsymbol{\theta} = \eta\delta_t \mathbf{e}_t \tag{16.22}$$

where the temporal difference error is

$$\delta_t = r_{t+1} + \gamma Q(s_{t+1}, a_{t+1}) - Q(s_t, a_t)$$

and the vector of eligibilities of parameters are updated as

$$\mathbf{e}_t = \gamma\lambda\mathbf{e}_{t-1} + \nabla_{\boldsymbol{\theta}_t} Q(s_t, a_t) \tag{16.23}$$

with $\mathbf{e}_0$ all zeros. In the case of a tabular algorithm, the eligibilities are stored for the state-action pairs because they are the parameters (stored as a table). In the case of an estimator, eligibility is associated with the parameters of the estimator. We also note that this is very similar to the momentum method for stabilizing backpropagation (section 11.8.1). The difference is that in the case of momentum previous weight changes are remembered, whereas here previous gradient vectors are remembered.

Depending on the model used for $Q(s_t, a_t)$, for example, a neural network, we plug its gradient vector in equation 16.23.

In theory, any regression method can be used to train the Q function but the particular task has a number of requirements: First, it should allow generalization, that is we really need to guarantee that similar states and actions have similar Q values. This also requires a good coding of s and a, as in any application, to make the similarities apparent. Second, reinforcement learning updates provide instances one by one and not as a whole training set, and the learning algorithm should be able to do individual updates to learn the new instance without forgetting what has been learned before. For example, a multilayer perceptron using backpropagation can be trained with a single instance only if a small learning rate is used. Or, such instances may be collected to form a training set and learned altogether but this slows down learning as no learning happens while a sufficiently large sample is being collected.

Because of these reasons, it seems a good idea to use local learners to learn the Q values. In such methods, for example, radial basis functions, information is localized and when a new instance is learned, only a local part of the learner is updated without possibly corrupting the information in another part. The same requirements apply if we are estimating the state values as $V(s_t|\boldsymbol{\theta})$.

16.7 Partially Observable States

In certain applications, the agent does not know the state exactly. It is equipped with sensors that return an *observation* using which the agent

should estimate the state. Let us say we have a robot which navigates in a room. The robot may not know its exact location in the room, or what else is there in the room. The robot may have a camera with which sensory observations are recorded. This does not tell the robot its state exactly but gives some indication as to its likely state. For example the robot, may only know that there is a wall to its right.

The setting is like a Markov decision process, except that after taking an action a_t, the new state s_{t+1} is not known but we have an observation o_{t+1} which is a stochastic function of s_t and a_t: $p(o_{t+1}|s_t, a_t)$. This is called a *partially observable MDP* (POMDP). If $o_{t+1} = s_{t+1}$, then POMDP reduces to the MDP. This is just like the distinction between observable and hidden Markov models and the solution is similar; that is, from the observation, we need to infer the state (or rather a probability distribution for the states) and then act based on this. If the agent believes that it is in state s_1 with probability 0.4 and in state s_2 with probability 0.6, then the value of any action is 0.4 times the value of the action in s_1 plus 0.6 times the value of the action in s_2.

PARTIALLY OBSERVABLE MDP

The Markov property does not hold for observations: The next state observation does not only depend on the current action and observation. When there is limited observation, two states may appear the same but are different and if these two states require different actions, this can lead to a loss of performance, as measured by the cumulative reward. The agent should somehow compress the past trajectory into a current unique state estimate. These past observations can also be taken into account by taking a past window of observations as input to the policy or one can use a recurrent neural network (section 11.12.2) to maintain the state without forgetting past observations.

At any time, the agent may calculate the most likely state and take an action accordingly. Or it may take an action to gather information and reduce uncertainty, for example, search for a landmark, or stop to ask for direction. This implies the importance of the *value of information* (section 3.6) and indeed POMDPs can be modeled as *dynamic* influence diagrams (section 3.8). The agent chooses between actions based on the amount of information they provide, the amount of reward they produce, and how they change the state of the environment.

BELIEF STATE

To keep the process Markov, the agent keeps an internal *belief state* b_t that summarizes its experience (see figure 16.9). The agent has a *state estimator* that updates the belief state b_{t+1} based on the last action a_t, current observation o_{t+1}, and its previous belief state b_t. There is a pol-

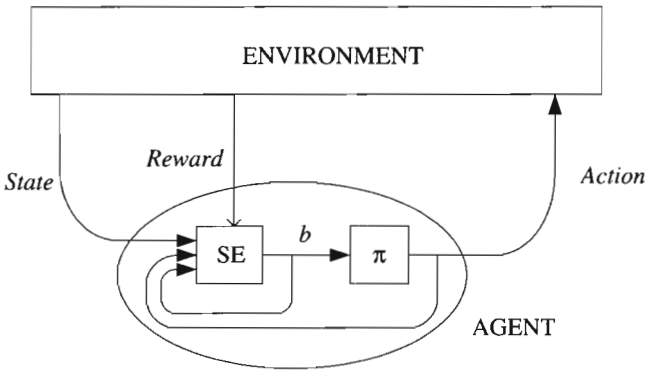

Figure 16.9 In the case of a partially observable environment, the agent has a state estimator (SE) that keeps an internal belief state b and the policy π generates actions based on the belief states.

icy π that generates the next action a_{t+1} based on this belief state, as opposed to the real state that we had in a completely observable environment. The belief state is a probability distribution over states of the environment given the initial belief state (before we did any actions) and the past observation-action history of the agent (without leaving out any information that could improve agent's performance). Q learning in such a case involves the belief state-action pair values, instead of the actual state-action pairs:

$$Q(b_t, a_t) = E[r_{t+1}] + \gamma \sum_{b_{t+1}} P(b_{t+1}|b_t, a_t) V(b_{t+1}) \tag{16.24}$$

An algorithm is given in (Kaelbling, Littman, and Cassandra 1998) but unfortunately due to its high computational complexity, it can be solved exactly for only tens of states. Otherwise, one needs to resort to an algorithm that approximates the value function $V(b_{t+1})$; a review of such algorithms is given in Hauskrecht 2000.

16.8 Notes

More information on reinforcement learning can be found in the textbook by Sutton and Barto (1998) that discusses all the aspects, learning algorithms, and several applications. A comprehensive tutorial is Kaelbling, Littman, and Moore 1996.

Dynamic programming methods are discussed in Bertsekas 1987 and in Bertsekas and Tsitsiklis 1996, and TD(λ) and Q-learning can be seen as stochastic approximations to dynamic programming (Jaakkola, Jordan, and Singh 1994). Reinforcement learning has two advantages over classical dynamic programming: First, as they learn, they can focus on the parts of the space that are important and ignore the rest; and second, they can employ function approximation methods to represent knowledge that allows them to generalize and learn faster.

LEARNING AUTOMATA

A related field is that of *learning automata* (Narendra and Thathachar 1974), which are finite state machines that learn by trial and error for solving problems like the K-armed bandit. The setting we have here is also the topic of optimal control where there is a controller (agent) taking actions in a plant (environment) that minimize cost (maximize reward).

The earliest use of temporal difference method was in Samuel's checkers program written in 1959 (Sutton and Barto 1998). For every two successive positions in a game, the two board states are evaluated by the board evaluation function that then causes an update to decrease the difference. There has been much work on games because games are both easily defined and challenging. A game like chess can easily be simulated: the allowed moves are formal, and the goal is well-defined. Despite the simplicity of defining the game, expert play is quite difficult.

TD-GAMMON

One of the most impressive application of reinforcement learning is the *TD-Gammon* program that learns to play backgammon by playing against itself (Tesauro 1995). This program is superior to the previous neurogammon program also developed by Tesauro, which was trained in a supervised manner based on plays by experts. Backgammon is a complex task with approximately 10^{20} states, and there is randomness due to the roll of dice. Using the TD(λ) algorithm, the program achieves master level play after playing 1,500,000 games against a copy of itself.

Another interesting application is in *job shop scheduling*, or finding a schedule of tasks satisfying temporal and resource constraints (Zhang and Dietterich 1996). Some tasks have to be finished before others can be started, and two tasks requiring the same resource cannot be done simultaneously. Zhang and Dietterich used reinforcement learning to quickly find schedules that satisfy the constraints and are short. Each state is one schedule, actions are schedule modifications, and the program finds not only one good schedule but a schedule for a class of related scheduling problems.

Recently hierarchical methods have also been proposed where the prob-

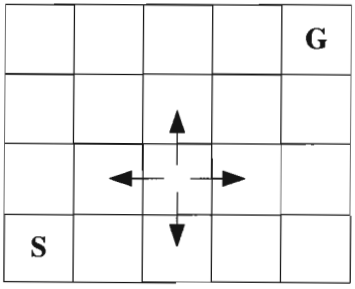

Figure 16.10 The grid world. The agent can move in the four compass directions starting from S. The goal state is G.

lem is decomposed into a set of subproblems. This has the advantage that policies learned for the subproblems can be shared for multiple problems, which accelerates learning of the new problem (Dietterich 2000). Each subproblem is simpler and learning them separately is faster. The disadvantage is that when they are combined, the policy may be suboptimal.

Though reinforcement learning algorithms are slower than supervised learning algorithms, it is clear that they have a wider variety of application and have the potential to construct better learning machines (Ballard 1997). They do not need any supervision and this may actually be better since then they are not biased by the teacher. For example, Tesauro's TD-Gammon program in certain circumstances came up with moves that turned out to be superior to those made by the best players. The field of reinforcement learning is developing rapidly and we may expect to see other impressive results in the near future.

16.9 Exercises

1. Given the grid world in figure 16.10, if the reward on reaching on the goal is 100 and $\gamma = 0.9$, calculate manually $Q^*(s,a)$, $V^*(S)$, and the actions of optimal policy.
2. With the same configuration given in exercise 1, use Q learning to learn the optimal policy.
3. In exercise 1, how does the optimal policy change if another goal state is added to the lower-right corner? What happens if a state of reward -100 (a very bad state) is defined in the lower-right corner?

4. Instead of having $\gamma < 1$, we can have $\gamma = 1$ but with a negative reward of $-c$ for all intermediate (nongoal) states. What is the difference?
5. In exercise 1, assume that the reward on arrival to the goal state is normal distributed with mean 100 and variance 40. Assume also that the actions are also stochastic in that when the robot advances in a direction, it moves in the intended direction with probability 0.5 and there is a 0.25 probability that it moves in one of the lateral directions. Learn $Q(s, a)$ in this case.
6. Assume we are estimating the value function for states $V(s)$ and that we want to use TD(λ) algorithm. Derive the tabular value iteration update.
7. Using equation 16.22, derive the weight update equations when a multilayer perceptron is used to estimate Q.
8. Give an example of a reinforcement learning application that can be modeled by a POMDP. Define the states, actions, observations, and reward.

A Probability

We review briefly the elements of probability, the concept of a random variable, and example distributions.

A.1 Elements of Probability

A RANDOM experiment is one whose outcome is not predictable with certainty in advance (Ross 1987; Casella and Berger 1990). The set of all possible outcomes is known as the *sample space* S. A sample space is *discrete* if it consists of a finite (or countably infinite) set of outcomes; otherwise it is *continuous*. Any subset E of S is an *event*. Events are sets, and we can talk about their complement, intersection, union, and so forth.

One interpretation of probability is as a *frequency:* When an experiment is continually repeated under the exact same conditions, for any event E, the proportion of time that the outcome is in E approaches some constant value. This constant limiting frequency is the probability of the event, and we denote it as $P(E)$.

Probability sometimes is interpreted as a *degree of belief.* For example, when we speak of Turkey's probability of winning the World Soccer Cup in 2006, we do not mean a frequency of occurrence, since the championship will happen only once and it has not yet occurred (at the time of the writing of this book). What we mean in such a case is a subjective degree of belief in the occurrence of the event. Because it is subjective, different individuals may assign different probabilities to the same event.

A.1.1 Axioms of Probability

Axioms ensure that the probabilities assigned in a random experiment can be interpreted as relative frequencies and that the assignments are consistent with our intuitive understanding of relationships among relative frequencies:

1. $0 \leq P(E) \leq 1$. If E_1 is an event that cannot possibly occur then $P(E_1) = 0$. If E_2 is sure to occur, $P(E_2) = 1$.
2. S is the sample space containing all possible outcomes, $P(S) = 1$.
3. If $E_i, i = 1, \ldots, n$ are mutually exclusive (i.e., if they cannot occur at the same time, as in $E_i \cap E_j = \emptyset, j \neq i$, where $\emptyset$ is the *null event* that does not contain any possible outcomes) we have

$$P\left(\bigcup_{i=1}^{n} E_i\right) = \sum_{i=1}^{n} P(E_i) \tag{A.1}$$

For example, letting E^c denote the *complement* of E, consisting of all possible outcomes in S that are not in E, we have $E \cap E^C = \emptyset$ and

$$P(E \cup E^c) = P(E) + P(E^c) = 1$$
$$P(E^c) = 1 - P(E)$$

If the intersection of E and F is not empty, we have

$$P(E \cup F) = P(E) + P(F) - P(E \cap F) \tag{A.2}$$

A.1.2 Conditional Probability

$P(E|F)$ is the probability of the occurrence of event E given that F occurred and is given as

$$P(E|F) = \frac{P(E \cap F)}{P(F)} \tag{A.3}$$

Knowing that F occurred reduces the sample space to F, and the part of it where E also occurred is $E \cap F$. Note that equation A.3 is well-defined only if $P(F) > 0$. Because $\cap$ is commutative, we have

$$P(E \cap F) = P(E|F)P(F) = P(F|E)P(E)$$

which gives us *Bayes' formula:*

$$P(F|E) = \frac{P(E|F)P(F)}{P(E)} \tag{A.4}$$

When F_i are mutually exclusive and exhaustive, namely, $\bigcup_{i=1}^{n} F_i = S$

$$E = \bigcup_{i=1}^{n} E \cap F_i$$

$$P(E) = \sum_{i=1}^{n} P(E \cap F_i) = \sum_{i=1}^{n} P(E|F_i)P(F_i) \tag{A.5}$$

Bayes' formula allows us to write

$$P(F_i|E) = \frac{P(E \cap F_i)}{P(E)} = \frac{P(E|F_i)P(F_i)}{\sum_j P(E|F_j)P(F_j)} \tag{A.6}$$

If E and F are *independent,* we have $P(E|F) = P(E)$ and thus

$$P(E \cap F) = P(E)P(F) \tag{A.7}$$

That is, knowledge of whether F has occurred does not change the probability that E occurs.

A.2 Random Variables

A *random variable* is a function that assigns a number to each outcome in the sample space of a random experiment.

A.2.1 Probability Distribution and Density Functions

The *probability distribution function* $F(\cdot)$ of a random variable X for any real number a is

$$F(a) = P\{X \leq a\} \tag{A.8}$$

and we have

$$P\{a < X \leq b\} = F(b) - F(a) \tag{A.9}$$

If X is a discrete random variable

$$F(a) = \sum_{\forall x \leq a} P(x) \tag{A.10}$$

where $P(\cdot)$ is the *probability mass function* defined as $P(a) = P\{X = a\}$. If X is a *continuous* random variable, $p(\cdot)$ is the *probability density function* such that

$$F(a) = \int_{-\infty}^{a} p(x)dx \tag{A.11}$$

A.2.2 Joint Distribution and Density Functions

In certain experiments, we may be interested in the relationship between two or more random variables, and we use the *joint* probability distribution and density functions of X and Y satisfying

$$F(x, y) = P\{X \leq x, Y \leq y\} \tag{A.12}$$

Individual *marginal* distributions and densities can be computed by marginalizing, namely, summing over the free variable:

$$F_X(x) = P\{X \leq x\} = P\{X \leq x, Y \leq \infty\} = F(x, \infty) \tag{A.13}$$

In the discrete case, we write

$$P(X = x) = \sum_j P(x, y_j) \tag{A.14}$$

and in the continuous case, we have

$$p_X(x) = \int_{-\infty}^{\infty} p(x, y)dy \tag{A.15}$$

If X and Y are *independent*, we have

$$p(x, y) = p_X(x)p_Y(y) \tag{A.16}$$

These can be generalized in a straightforward manner to more than two random variables.

A.2.3 Conditional Distributions

When X and Y are random variables

$$P_{X|Y}(x|y) = P\{X = x|Y = y\} = \frac{P\{X = x, Y = y\}}{P\{Y = y\}} = \frac{P(x, y)}{P_Y(y)} \tag{A.17}$$

A.2.4 Bayes' Rule

When two random variables are jointly distributed with the value of one known, the probability that the other takes a given value can be computed using *Bayes' rule:*

$$P(y|x) = \frac{P(x|y)P_Y(y)}{P_X(x)} = \frac{P(x|y)P_Y(y)}{\sum_y P(x|y)P_Y(y)} \tag{A.18}$$

Or, in words

$$\text{posterior} = \frac{\text{likelihood} \times \text{prior}}{\text{evidence}} \tag{A.19}$$

Note that the denominator is obtained by summing (or integrating if y is continuous) the numerator over all possible y values. The "shape" of $p(y|x)$ depends on the numerator with denominator as a normalizing factor to guarantee that $p(y|x)$ sum to 1. Bayes' rule allows us to modify a prior probability into a posterior probability by taking information provided by x into account.

Bayes' rule inverts dependencies, allowing us to compute $p(y|x)$ if $p(x|y)$ is known. Suppose that y is the "cause" of x, like y going on summer vacation and x having a suntan. Then $p(x|y)$ is the probability that someone who is known to have gone on summer vacation has a suntan. This is the *causal* (or predictive) way. Bayes' rule allows us a *diagnostic* approach by allowing us to compute $p(y|x)$: namely, the probability that someone who is known to have a suntan, has gone on summer vacation. Then $p(y)$ is the general probability of anyone's going on summer vacation and $p(x)$ is the probability that anyone has a suntan, including both those who have gone on summer vacation and those who have not.

A.2.5 Expectation

Expectation, expected value, or *mean* of a random variable X, denoted by $E[X]$, is the average value of X in a large number of experiments:

$$E[X] = \begin{cases} \sum_i x_i P(x_i) & \text{if } X \text{ is discrete} \\ \int x p(x) dx & \text{if } X \text{ is continuous} \end{cases} \tag{A.20}$$

It is a weighted average where each value is weighted by the probability that X takes that value. It has the following properties ($a, b \in \Re$):

$$\begin{aligned} E[aX + b] &= aE[X] + b \\ E[X + Y] &= E[X] + E[Y] \end{aligned} \tag{A.21}$$

For any real-valued function $g(\cdot)$, the expected value is

$$E[g(X)] = \begin{cases} \sum_i g(x_i)P(x_i) & \text{if } X \text{ is discrete} \\ \int g(x)p(x)dx & \text{if } X \text{ is continuous} \end{cases} \tag{A.22}$$

A special $g(x) = x^n$, called the nth moment of X, is defined as

$$E[X^n] = \begin{cases} \sum_i x_i^n P(x_i) & \text{if } X \text{ is discrete} \\ \int x^n p(x)dx & \text{if } X \text{ is continuous} \end{cases} \tag{A.23}$$

Mean is the first moment and is denoted by μ.

A.2.6 Variance

Variance measures how much X varies around the expected value. If $\mu \equiv E[X]$, the variance is defined as

$$\text{Var}(X) = E[(X-\mu)^2] = E[X^2] - \mu^2 \tag{A.24}$$

Variance is the second moment minus the square of the first moment. Variance, denoted by σ^2, satisfies the following property ($a, b \in \Re$):

$$\text{Var}(aX+b) = a^2\text{Var}(X) \tag{A.25}$$

$\sqrt{\text{Var}(X)}$ is called the *standard deviation* and is denoted by σ. Standard deviation has the same unit as X and is easier to interpret than variance.

Covariance indicates the relationship between two random variables. If the occurrence of X makes Y more likely to occur, then the covariance is positive; it is negative if X's occurrence makes Y less likely to happen and is 0 if there is no dependence.

$$\text{Cov}(X,Y) = E[(X-\mu_X)(Y-\mu_Y)] = E[XY] - \mu_X\mu_Y \tag{A.26}$$

where $\mu_X \equiv E[X]$ and $\mu_Y \equiv E[Y]$. Some other properties are

$$\begin{aligned} \text{Cov}(X,Y) &= \text{Cov}(Y,X) \\ \text{Cov}(X,X) &= \text{Var}(X) \\ \text{Cov}(X+Z,Y) &= \text{Cov}(X,Y) + \text{Cov}(Z,Y) \end{aligned}$$

$$\text{Cov}\left(\sum_i X_i, Y\right) = \sum_i \text{Cov}(X_i, Y) \tag{A.27}$$

$$\text{Var}(X+Y) = \text{Var}(X) + \text{Var}(Y) + 2\text{Cov}(X,Y) \tag{A.28}$$

$$\text{Var}\left(\sum_i X_i\right) = \sum_i \text{Var}(X_i) + \sum_i \sum_{j \neq i} \text{Cov}(X_i, X_j) \tag{A.29}$$

If X and Y are independent, $E[XY] = E[X]E[Y] = \mu_X\mu_Y$ and $\text{Cov}(X, Y) = 0$. Thus if X_i are independent

$$\text{Var}\left(\sum_i X_i\right) = \sum_i \text{Var}(X_i) \tag{A.30}$$

Correlation is a normalized, dimensionless quantity that is always between -1 and 1:

$$\text{Corr}(X, Y) = \frac{\text{Cov}(X, Y)}{\sqrt{\text{Var}(X)\text{Var}(Y)}} \tag{A.31}$$

A.2.7 Weak Law of Large Numbers

Let $\mathcal{X} = \{X^t\}_{t=1}^N$ be a set of independent and identically distributed (iid) random variables each having mean μ and a finite variance σ^2. Then for any $\epsilon > 0$

$$P\left\{\left|\frac{\sum_t X^t}{N} - \mu\right| > \epsilon\right\} \to 0 \text{ as } N \to \infty \tag{A.32}$$

That is, the average of N trials converges to the mean as N increases.

A.3 Special Random Variables

There are certain types of random variables that occur so frequently that names are given to them.

A.3.1 Bernoulli Distribution

A trial is performed whose outcome is either a "success" or a "failure." The random variable X is a 0/1 indicator variable and takes the value 1 for a success outcome and is 0 otherwise. p is the probability that the result of trial is a success. Then

$$P\{X = 1\} = p \text{ and } P\{X = 0\} = 1 - p \tag{A.33}$$

which can equivalently be written as

$$P\{X = i\} = p^i(1 - p)^{1-i}, i = 0, 1 \tag{A.34}$$

If X is Bernoulli, its expected value and variance are

$$E[X] = p,\ \text{Var}(X) = p(1 - p) \tag{A.35}$$

A.3.2 Binomial Distribution

If N identical independent Bernoulli trials are made, the random variable X that represents the number of successes that occurs in N trials is binomial distributed. The probability that there are i successes is

$$P\{X = i\} = \binom{N}{i} p^i (1-p)^{N-i}, i = 0 \ldots N \tag{A.36}$$

If X is binomial, its expected value and variance are

$$E[X] = Np, \ \mathrm{Var}(X) = Np(1-p) \tag{A.37}$$

A.3.3 Multinomial Distribution

Consider a generalization of Bernoulli where instead of two states, the outcome of a random event is one of K mutually exclusive and exhaustive states, each of which has a probability of occurring p_i where $\sum_{i=1}^{K} p_i = 1$. Suppose that N such trials are made where outcome i occurred N_i times with $\sum_{i=1}^{k} N_i = N$. Then the joint distribution of $N_1, N_2, \ldots, N_K$ is multinomial:

$$P(N_1, N_2, \ldots, N_K) = N! \prod_{i=1}^{K} \frac{p_i^{N_i}}{N_i!} \tag{A.38}$$

A special case is when $N = 1$; only one trial is made. Then N_i are 0/1 indicator variables of which only one of them is 1 and all others are 0. Then equation A.38 reduces to

$$P(N_1, N_2, \ldots, N_K) = \prod_{i=1}^{K} p_i^{N_i} \tag{A.39}$$

A.3.4 Uniform Distribution

X is uniformly distributed over the interval $[a, b]$ if its density function is given by

$$p(x) = \begin{cases} \frac{1}{b-a} & \text{if } a \le x \le b \\ 0 & \text{otherwise} \end{cases} \tag{A.40}$$

If X is uniform, its expected value and variance are

$$E[X] = \frac{a+b}{2}, \ \mathrm{Var}(X) = \frac{(b-a)^2}{12} \tag{A.41}$$

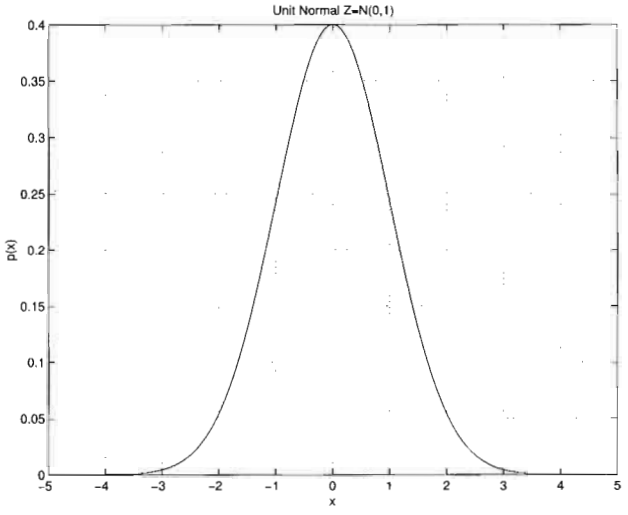

Figure A.1 Probability density function of $\mathcal{Z}$, the unit normal distribution.

A.3.5 Normal (Gaussian) Distribution

X is normal or Gaussian distributed with mean μ and variance σ^2, denoted as $\mathcal{N}(\mu, \sigma^2)$, if its density function is

$$p(x) = \frac{1}{\sqrt{2\pi}\sigma} \exp\left[-\frac{(x-\mu)^2}{2\sigma^2}\right], -\infty < x < \infty \tag{A.42}$$

Many random phenomena obey the bell-shaped normal distribution, at least approximately, and many observations from nature can be seen as a continuous, slightly different versions of a typical value—that is probably why it is called the *normal* distribution. In such a case, μ represents the typical value and σ defines how much instances vary around the prototypical value.

68.27 percent lie in $(\mu - \sigma, \mu + \sigma)$, 95.45 percent in $(\mu - 2\sigma, \mu + 2\sigma)$ and 99.73 percent in $(\mu - 3\sigma, \mu + 3\sigma)$. Thus $P\{|x - \mu| < 3\sigma\} \approx .99$. For practical purposes, $p(x) \approx 0$ if $x < \mu - 3\sigma$ or $x > \mu + 3\sigma$. $\mathcal{Z}$ is unit normal, namely, $\mathcal{N}(0, 1)$ (see figure A.1) and its density is written as

$$p_Z(x) = \frac{1}{\sqrt{2\pi}} \exp\left[-\frac{x^2}{2}\right] \tag{A.43}$$

If $X \sim \mathcal{N}(\mu, \sigma^2)$ and $Y = aX + b$, then $Y \sim \mathcal{N}(a\mu + b, a^2\sigma^2)$. The sum of independent normal variables is also normal with $\mu = \sum_i \mu_i$ and $\sigma^2 = \sum_i \sigma_i^2$. If X is $\mathcal{N}(\mu, \sigma^2)$, then

$$\frac{X - \mu}{\sigma} \sim \mathcal{Z} \tag{A.44}$$

This is called z-normalization.

CENTRAL LIMIT THEOREM

Let $X_1, X_2, \ldots, X_N$ be a set of iid random variables all having mean μ and variance σ^2. Then the *central limit theorem* states that for large N, the distribution of

$$X_1 + X_2 + \ldots + X_N \tag{A.45}$$

is approximately $\mathcal{N}(N\mu, N\sigma^2)$. For example, if X is binomial with parameters (N, p), X can be written as the sum of N Bernoulli trials and $(X - Np)/\sqrt{Np(1-p)}$ is approximately unit normal.

Central limit theorem is also used to generate normally distributed random variables on computers. Programming languages have subroutines that return uniformly distributed (pseudo-)random numbers in the range $[0, 1]$. When U_i are such random variables, $\sum_{i=1}^{12} U_i - 6$ is approximately $\mathcal{Z}$.

Let us say $X^t \sim \mathcal{N}(\mu, \sigma^2)$. The estimated sample mean

$$m = \frac{\sum_{t=1}^{N} X^t}{N} \tag{A.46}$$

is also normal with mean μ and variance σ^2/N.

A.3.6 Chi-Square Distribution

If Z_i are independent unit normal random variables, then

$$X = Z_1^2 + Z_2^2 + \ldots + Z_n^2 \tag{A.47}$$

is chi-square with n degrees of freedom, namely, $X \sim \mathcal{X}_n^2$, with

$$E[X] = n, \ \mathrm{Var}(X) = 2n \tag{A.48}$$

When $X^t \sim \mathcal{N}(\mu, \sigma^2)$, the estimated sample variance is

$$S^2 = \frac{\sum_t (X^t - m)^2}{N - 1} \tag{A.49}$$

and we have

$$(N-1)\frac{S^2}{\sigma^2} \sim \mathcal{X}_{N-1}^2 \tag{A.50}$$

It is also known that m and S^2 are independent.

A.3.7 *t* Distribution

If $Z \sim \mathcal{Z}$ and $X \sim \mathcal{X}^2_n$ are independent, then

$$T_n = \frac{Z}{\sqrt{X/n}} \tag{A.51}$$

is t-distributed with n degrees of freedom with

$$E[T_n] = 0, n > 1, \ \mathrm{Var}(T_n) = \frac{n}{n-2}, n > 2 \tag{A.52}$$

Like the unit normal density, t is symmetric around 0. As n becomes larger, t density becomes more and more like the unit normal, the difference being that t has thicker tails, indicating greater variability than does normal.

A.3.8 *F* Distribution

If $X_1 \sim \mathcal{X}^2_n$ and $X_2 \sim \mathcal{X}^2_m$ are independent chi-square random variables with n and m degrees of freedom respectively,

$$F_{n,m} = \frac{X_1/n}{X_2/m} \tag{A.53}$$

is F-distributed with n and m degrees of freedom with

$$E[F_{n,m}] = \frac{m}{m-2}, m > 2, \ \mathrm{Var}(F_{n,m}) = \frac{m^2(2m+2n-4)}{n(m-2)^2(m-4)}, m > 4 \tag{A.54}$$
